The content of cæsium-137 in human beings has of course a close relationship to the content of this isotope in the diet, which in turn partially depends on the local fall-out level. It has been established that the distribution of stratospheric fall-out depends on the geographical location, with higher concentrations in the northern hemisphere around 30°–60° N. The fall-out is also greatly influenced by the local rainfall.

Data on the cæsium-137 content of milk, which is a significant part of the diet, have indicated a larger content of cæsium-137 in milk produced in Norway[10] and Finland[11] than in milk from many other countries. This is especially true for milk from the western part of Norway. The reasons for this difference in cæsium content between eastern and western Norway are not well understood. It is probable that the amount and nature of the rainfall is at least one cause. The different grazing habits of cows in these two areas probably also contribute to the difference. Other dairy products used in the daily diet in Norway, among them cheese, have been studied, and pure goat's cheese produced in the western and northern parts of Norway in 1960 have shown values ranging up to 41 nc. cæsium-137/kgm. cheese. A blended goat's cheese is also produced in Norway which is made of 35 per cent goat's milk and 65 per cent cow's milk. This type of cheese is produced in parts of the country having lower cæsium-137-contents. Consequently the blended goat's cheese has only 15–20 per cent of the cæsium-137 content of the pure goat's cheese. In this article and in Table 1 only pure goat's cheese is considered. Table 1 lists the amount of pure goat's cheese eaten, according to the subject's own estimate. However, the difference between the pure and the blended goat's cheese is not popularly understood, and some of these estimates may include blended goat's cheese. Measurements carried out on the cæsium-137 content in other major food products have shown considerably lower values except for reindeer meat, which seems to have activities of the same order as goat's cheese.

Preliminary measurements made at the Radiation Physics Department in Lund of the cæsium-137 content in five Norwegians indicated that Norwegian inhabitants could have higher cæsium-137 body-burdens than those reported for people elsewhere. Due to the fact that no whole-body counter exists in Norway, it was decided to send another group of Norwegians to Lund to have their body radioactivity measured in the whole-body counter there. These people, mostly 20–30 years of age, were arbitrarily selected, with one group of 6 persons from Bergen (at the west coast of Norway 60° N.) and a group of 15 from Oslo (60° N.). None was occupationally exposed to cæsium-137. A few, 3 from Bergen and 5 from Oslo, stated that they regularly used pure goat's cheese in their daily diet.

The measurements were made in an iron room with subject sitting in the 'Argonne chair' position, the detector unit was a 5-in. diameter × 4 in. thick sodium iodide (thallium) crystal and a multichannel pulse-height analyser.

The results of the measurements are shown in Table 1. This gives the measured contents of cæsium-137 in nc. and the number of gm. potassium, together with approximate daily consumption of milk (litres) and pure goat's cheese (gm.).

As can be seen from Table 1, the average cæsium-137/potassium ratio (184 pc./gm. potassium) in the people from Oslo is considerably higher than the 1960 values of ~ 50 pc./gm. potassium reported elsewhere. This can be compared directly with the average cæsium-137/potassium ratio of a group of people from Lund, Sweden (56° N.), of 76 pc./gm. potassium. The average value of the cæsium-137/potassium ratio of 477 pc./gm. potassium found for the Bergen group is even higher. With one exception (I. L.) the values for the Bergen group are well above those of the Oslo people. Two of the subjects, G. G. and I. K., seem to have surprisingly low cæsium-137/potassium ratios in view of their milk and goat's cheese consumption. It has been impossible to determine what type and source of goat's cheese these subjects used; but it is probable that they used the blended type.

It is generally accepted that 55–60 per cent of cæsium-137 in the human body is caused by consumption of dairy products[12,13]. It is also stated[12] that people in the United States contain a substantially constant amount of cæsium-137 due to non-dairy sources and that the remaining fraction of their cæsium-137 burden is directly proportional to their milk input. Due to this fact and because milk constitutes a significant part of children's diet, special interest has been focused on the radioactive content in this material.

Milk samples from different parts of Norway have been analysed for their content of cæsium-137 [10,14]. Beside the usual seasonal variations which are generally established, large variations are found between samples from the western and eastern parts of the country, amounting to almost a factor of 30 (Möre, on the west coast of Norway, about 900 pc./l. Oslo, about 30 pc./l. September 1960). These variations will, on a smaller scale, also show up in the population and to some extent explain the difference between the cæsium-137-level in the Bergen people and the Oslo people. The milk distribution systems for both areas are based on local central dairies; people within the same district having equal daily intake of milk should therefore be exposed to approximately equal amounts of radioactive contaminants and thus show nearly equal body burdens. As can be seen from the measured data, this condition does not hold. A man from Bergen (K. M.) and a woman from Oslo (B. M.) show body-burdens which are almost a factor of 2 higher than the mean values obtained for people in the respective districts. These two people regularly consumed rather large quantities of pure goat's cheese; it is concluded that the excess quantity of cæsium-137 in these two cases, to some extent, can be attributed to the cheese consumption.

The cæsium-137-levels in goat's cheese from different parts of the country show even larger variations than those that have been reported for cow's milk. A calculation of the cæsium-137 excess in people, due to the cheese intake, would require a complete knowledge about place and time for production of the cheese. This has been an impossible task in all cases except for one single person (B. M.), who consumed pure goat's cheese from Hallingdal only. The content of cæsium-137 in this particular cheese has been measured. The calculation of cæsium-137 excess due to cheese consumption will, however, require detailed knowledge about the discrimination factor of cæsium-137 in going from diet to man, and the biological half-time of this isotope in the human body. Studies of the discrimination factor for cæsium-137 have been reported in the literature and values ranging from 1·8 to 3·5 have been given[3]. The biological half-time, which is closely related to the discrimination factor, will show similar variation, and reports indicate values ranging from 143 to 81 days. Any of these figures might be used, yielding an excess amount of cæsium-137 due to cheese intake ranging between rather wide limits. As a compromise calculations were carried out applying a discrimination factor of 2 and a biological half-time of 100 days. The result of this calculation gives a value of 12·2 nc. cæsium-137 for B. M. due to goat's cheese consumption. This value should be compared with 27·2 nc. from Table 1. The difference 15 nc. between the mentioned figures should then be responsible for cæsium-137 intake due to other food products; this value seems to be in reasonable agreement with measured data for females not eating goat's cheese given in Table 1.

The radiation exposure for the extreme case from Bergen was calculated using the formula given by the International Commission on Radiological Protection[16] and turned out to be 0·31 mr./week. This dose is comparable to the radiation dose caused by the potassium-40, which in this case amounts to 16 mr./year or 0·3 mr./week.

It is of interest to estimate the body-burden due to a daily intake of 50 gm. of pure goat's cheese containing 41 nc. cæsium-137/kgm., which actually has been measured. This intake of cheese is considered to be quite normal in Norway. Assuming again a discrimination factor of 2 for cæsium in relation to potassium and an elimination-rate of 0·7 per cent a day (100 days biological half-life), this will in one year accumulate to 135 nc. cæsium-137. The total body irradiation caused by this amount will be of the order of 0·38 mr./week or 20 mr./year.

This investigation was carried out while one of us (R. C. McC.) was holding a Postdoctoral Fellowship of the National Cancer Institute, U.S. Public Health Service.

NEWS and VIEWS

Sir Frederick Gowland Hopkins (1861–1947)

To mark the centenary of the birth (June 30, 1861) of Sir Frederick Gowland Hopkins, "the father of British biochemistry", and as a tribute to one "whose services to nutrition enriched the well-being of mankind", Messrs. Van den Berghs, Ltd., manufacturers of vitaminized margarine, have published a 26-page memoir. It has been written by Prof. Ernest Baldwin, a former colleague of Hopkins, and it is a moving account of Hopkins as a great scientist and as a most lovable man. The booklet, which contains a reproduction taken from the well-known portrait of Hopkins owned by the Royal Society, can be obtained from Messrs. Van den Berghs, Ltd., Kildare House, Dorset Rise, London, E.C.4.

Chemistry in University College, Dublin : Prof. Eva M. Philbin

Dr. Eva M. Philbin, senior lecturer in organic chemistry in University College, Dublin, has been appointed, in succession to the late Prof. J. Algar, to the chair of organic chemistry tenable in that College. Prof. Philbin graduated with first-class honours in chemistry at University College, Galway, and afterwards was awarded the degrees of Ph.D. and D.Sc. in the National University of Ireland. After a time in industry, Prof. Philbin joined the staff of University College, Dublin, in 1945, and was later appointed senior lecturer in organic chemistry. Her research interests have been mainly in the field of flavonoids, though recently she has moved on to investigations relative to the stereochemistry of pyrans. She has held visiting and research fellowships in the United States, and at Zurich, with Prof. V. Prelog.

Agriculture at Bangor : Prof. E. J. Roberts

Prof. E. J. Roberts retires this year from the chair of agriculture at Bangor, after sixteen years of distinguished service as a teacher and a prominent figure in the farming world. He comes from the Vale of Clwyd, and graduated with honours in chemistry at Bangor in 1917. After a short period in the Navy as sub-lieutenant, he proceeded to the School of Agriculture at Cambridge, for postgraduate work under the late Prof. T. B. Wood. He was appointed lecturer in agriculture at Bangor in 1922. At the outbreak of the Second World War he was seconded as agricultural executive officer for Denbighshire. In 1942 he was appointed to the chair of agriculture at Aberystwyth, returning to Bangor when that professorship fell vacant in 1945.

Roberts's research interests have covered a wide range of problems in animal husbandry; among these were lactations of various breeds of dairy cows, flushing and fat-lamb production from grassland, and the breeding of polled Friesians and Welsh Blacks. In 1936 he was seconded to the Agricultural Research Council to make a detailed survey of grass-drying, and the monograph he produced was the most comprehensive of its kind on this subject. He has served on numerous bodies concerned with agriculture, for example, the Agricultural Improvement Council, Hill Farming Committee. the Sub-committee on Agriculture of the University Grants Committee, and the Welsh Joint Education Committee. The Arton Wilson Report (1956) on the Provincial and Local Organization and Procedures of the Ministry of Agriculture, Fisheries and Food also bears his name among its signatures. At Bangor, during the past ten years, he has carried out, by the aid of moneys from the University Grants Committee, an extensive scheme of remodelling and adaptation of the College Farm to form an efficient teaching unit.

Prof. I. A. McK. Lucas

Mr. Ian A. McK. Lucas succeeds Prof. Roberts at the comparatively early age of thirty-four. A graduate in agriculture of the University of Reading, he was a prizeman in agriculture. During 1947–49 he held a Ministry of Agriculture postgraduate scholarship in the Nutrition Department of Macdonald College of McGill University. There he took his M.Sc. under Prof. E. W. Crampton. After a short period as assistant lecturer in agricultural chemistry at Harper Adams Agricultural College, Prof. Lucas in 1950 joined the Applied Nutrition Department of the Rowett Research Institute as head of its section on pig nutrition, which post he now holds with distinction and with the rank of principal scientific officer. For a year (1957–58) Lucas, on study leave, held a New Zealand Department of Scientific and Industrial Research Fellowship at Ruakura Animal Research Station, where he broadened his experience by conducting experiments on grazing cattle and sheep. For six weeks thereafter he toured Australia at the invitation of the Australian Meat Board. He is the author of some thirty-two papers on various aspects of animal nutrition, mainly those concerned with the physiology of nutrition of the pig, particularly during early growth. Lucas is at present technical secretary of the Agricultural Research Council's Technical Committee on Nutrient Requirements of Farm Livestock and of its Working Party on Terminology. He is also a member of the Working Party on Pigs. Lucas also serves as a member of the Pig Commission of the European Society of Animal Production.

Presidency of the Mellon Institute: Dr. P. C. Cross

Dr. Paul C. Cross, of the University of Washington (Seattle), has been appointed president and chief executive officer of the Mellon Institute. Dr. Cross, a native of Bruin (Butler County), Pa., has been professor and executive officer of the Department of Chemistry of the University of Washington since 1949. He will assume his new post on September 1. He was born on July 19, 1907, received his bachelor's degree from Geneva College in 1928, and his doctor's degree from the University of Wisconsin in 1932. Afterwards, he held research fellowships at Wisconsin, the California Institute of Technology, and Stanford University. He became an assistant professor at Stanford in 1926, and in 1938 joined Brown University as an associate professor. During 1942–49 he served successively as professor, director of the Metcalf Research Laboratory, and chairman of the Chemistry Department at Brown University.

Department of Technical Co-operation

THE Department of Technical Co-operation came into being on July 24. The Minister in charge is Mr. Dennis Vosper, who will be known as the Secretary for Technical Co-operation. The director-general—the permanent head of the Department—is Sir Andrew Cohen. The Department's headquarters are at Carlton House Terrace, London, S.W.1. The new Department is taking over present work on technical assistance performed by the three overseas departments (the Foreign Office, the Commonwealth Relations Office and the Colonial Office) and the Ministry of Labour, together with their present staffs engaged on this work. The object is to enable the United Kingdom to meet more effectively requests for technical assistance received from the Governments of developing countries inside and outside the Commonwealth. Among the main activities of the Department of Technical Co-operation will be the following: (i) Recruitment of staff for service with overseas Governments and international organizations. (ii) Arrangements for the training of such staff, including staff already in the service of overseas Governments. (iii) Administration of the Overseas Service Aid Scheme which was set out in the White Paper, *Service with Overseas Governments* (Cmnd. 1193). (iv) Responsibility for the work of the Directorate of Overseas (Geodetic and Topographic) Surveys and the Directorate of Overseas Geological Surveys. (v) Aspects of Commonwealth educational co-operation affecting the United Kingdom. (vi) Special technical assistance projects overseas undertaken at the request of the Governments concerned. (vii) The handling of requests from United Kingdom dependent territories for technical assistance (including the financing of such assistance) under the Colonial Development and Welfare Acts, and from Commonwealth and foreign countries and international agencies. (viii) Making arrangements for assistance in the field of research, principally on subjects of importance to United Kingdom dependent territories, or where the United Kingdom has a special contribution to make overseas. (ix) Supplementing the work of other organizations in assistance to overseas Governments in placing students in the United Kingdom. (x) Providing assistance in certain instances to overseas Governments on technical matters relating to air and surface transport, telecommunications and postal services. (xi) Provision to overseas Governments of specialist advice at their request on a wide variety of subjects, such as agriculture, education, fisheries and medicine. Apart from certain educational projects, the new Department will not be responsible for the provision of capital aid, which will remain the responsibility of the overseas Departments.

Research and Development in Scotland

THE Parliamentary Secretary for Science, Mr. D. Freeth, replying to questions in the House of Commons on July 11, said that of 77 applications for grants for special researches received in 1960 from Scotland by the four Research Councils, 61 were accepted. Receipts from Scottish industry during 1960–61 amounted to about 4 per cent of the total receipts from industry by the Department of Scientific and Industrial Research in respect of work done at its establishments. Of 105 postgraduate awards for training in science and technology tenable at universities and colleges in Scotland made by the Department in 1960, 17 were in biology and biochemistry, 6 in chemical engineering and metallurgy, 40 in chemistry, 5 each in electrical engineering and engineering, 3 in geology, 6 in mathematics, 22 in physics and 1 in the human sciences.

Effects of Insecticides on Birds

THE Minister of Agriculture, Fisheries and Food, Mr. C. Soames, stated in reply to a question in the House of Commons on July 3 that the report of the survey of the effects of insecticides on animal life in Britain had been discussed at a meeting on June 29 with all the organizations interested. The report showed that the widespread occurrence of deaths of birds was confined to springtime, and that the main trouble could be obviated by not using dressings containing dieldrin, aldrin and heptachlor for spring sowings. Accordingly, it had been agreed that, as from January 1 next, these dressings will not be used at all for spring-sown grain, and they will only be used for dressing autumn and winter wheat where there is real danger of attack from wheat bulb fly. These arrangements will operate under the terms of the Notification of Pesticides Scheme. It has also been agreed that the Ministry should continue its survey, and that the arrangements should be reviewed at a meeting in June 1962. Pressed on various points, Mr. Soames promised to consider carefully the recommendations of the Estimates Committee regarding the voluntary schemes, but his information was that they had worked.

Farm Buildings in Britain

IN reply to a question in the House of Lords on July 6, the Minister for Science, Lord Hailsham, said that the Government does not think that a case has been established for a Government farm buildings research centre, but the Agricultural Research Council is undertaking a survey of farm buildings in Great Britain and is issuing a bibliography of research publications on the subject. The Council, in co-operation with the farmers concerned, is also organizing experiments with buildings on farms and contributing towards their capital cost. Lord Hailsham said further that with the experimental scheme started last year, by which landowners interested in scientific experiment could receive a 50 per cent grant for genuinely experimental buildings, the owners had to work in co-operation with the Agricultural Research Council. This method, covering the whole of Britain, with its different types of farming, circumstances and climate, appears to offer much better value than a research centre and the scheme has given very promising results. Of 177 applications received, 27 had been accepted as suitable for grants, 8 withdrawn and 90 rejected; 52 are under consideration.

Bibliography of Farm Buildings Research 1945–58

THE Agricultural Research Council is compiling a general bibliography of research publications on farm buildings. This is the first bibliography of the subject to be compiled, and *Buildings for the Drying and Storage of Grain* is the fifth section of the bibliography to appear. It will be followed by a section dealing with buildings for the processing and storage of fodder and a general section which will deal with miscellaneous types of building and with the construction and maintenance of farm buildings. The bibliography regards farm buildings as part of farm equipment and gives references to any matter affecting their design, construction, economics and use. It includes the findings of scientific research, of such systematic but less-precise forms of investigation as surveys, and of field trials and similar developmental phases of new techniques. It includes information from any country where conditions are relevant to Great Britain. Abstracts of the original material and a review summarizing the main conclusions are provided. The present bibliography covers the period January 1, 1945, to April 30, 1958. The Council intends to keep it up to date by publishing supplementary bibliographies from time to time. *Buildings for the Drying and Storage of Grain* (3*s*., postage 3*d*.) is obtainable from the Agricultural Research Council, Cunard Building, 15 Regent Street, London, S.W.1.

Public Health as a World Problem

THE fourth report from the World Health Organization's Expert Committee on Public Health Administration, of which Sir John Charles is chairman, is entitled *The Planning of Public Health Services* (Technical Report Series, No. 215. Pp. 48. Geneva: World Health Organization; London: H.M.S.O., 1961. 2 Swiss francs; 3*s*. 6*d*.; 0.60 dollars). It reviews broadly the experience in this field of Ceylon, India, Czechoslovakia, the U.S.S.R., the United Arab Republic and the United Kingdom, before considering in detail the general principles of planning such services in countries at varying stages of development and with different social and economic systems, to which any planning must be related. Stress is laid on the use of surveys to secure the information on which planning must be based, the importance of securing full co-ordination and collaboration from the medical and other professions concerned and the interest and understanding of the general public. The determination of priorities and the choice of long-term targets are also necessary, and since planning is a continuous process arrangements should be made for continuous review and assessment, so that the health programme is kept constantly in line with changing conditions; and in this connexion the value of operational research is emphasized. It is no longer satisfactory to plan health services on an empirical basis, and further research in public health service is needed to provide indicators for assessing on a more scientific basis the level of public health, the efficiency of health services, standards, and the economics of disease and disability and their reduction.

National Foundation for Scientific Research, Belgium

THE thirty-third annual report of the Belgian National Foundation for Scientific Research, covering the year 1959–60, comprises chiefly alphabetical lists of recipients of grants and of their publications during the year, in which grants totalling 39 million francs were voted (Fonds National de la Recherche Scientifique. Trente-troisième Rapport Annuel, 1959–60. Pp. 284. Bruxelles: Fonds National de la Recherche Scientifique, 1961). Of this total, 382,500 francs was to the University of Ghent, 240,000 francs to the University of Liège, 730,000 francs to the University of Brussels and 850,000 francs to the University of Louvain. Special grants noted in the report include 1,000,000 francs to the Committee for the Study and Exploitation of Electronic Calculators; 1,875,000 francs for research programmes concerned with the technique of regulation (chemical processes and stochastic phenomena) of the transmission of heat, automobile suspension and the mechanics of flight; 300,000 francs for studies of the effect of *P*, *Q*, *R*, *S*, *ST* and *T* waves of the vectorial electrocardiogram of man, the dog and the rabbit; 2,175,000 francs for a study of dynamic and static deformations, stresses, vibrations and temperatures in construction; 500,000 francs for studies to determine the structure of natural products (sesquiterpenes, steroids, triterpenes and alkaloids); and 300,000 francs for a study of the diffusion of atoms and free radicals in the solid phase at 4° K. as a function of their masses. There is also a note on research during the year at the Jungfraujoch scientific station.

Teachers and Health Education

HEALTH education is not always recognized as a discipline of its own and given its appropriate place in the training of teachers. A new report (Joint WHO/Unesco Expert Committee on Teacher Preparation for Health Education. World Health Org. Tech. Rep. Ser., 1960. No. 193. Pp. 19. 1*s*. 9*d*. Published also in French and Spanish) provides a flexible framework of guiding principles for such training, which should take place not only through courses of instruction but also through the teacher's actual mode of life in his training institution, his contact with student health services, and his experiences when practising teaching. Health education in schools should be based on the health needs and interests of the children, the teacher having many opportunities for imparting it both directly and by the part he can play in the school health services and in planning for a healthy school. To enable him to make the most of his opportunities, he must have some knowledge of growth and development, personal and community health, school health practice, and methods of health education. The report discusses these subjects, the future teacher's life as a student in relation to his opportunities for health work and to student health services, practice teaching, and the education he acquires as a fully-fledged teacher. Other sections deal with planning of training for teachers in health education, the desirability of one person in each training institution being responsible for co-ordination of courses and activities in health education, and possible future national and international developments, studies and research in the subject.

Hospital Efficiency Studies

THE Ministry of Health has issued recently, to hospital authorities, a second set of *Abstracts of Efficiency in the Hospital Service*. The first set, comprising seven investigations, was published in April. The aim of the series is to enable all hospitals to profit from simplification, improvements and money-saving ideas which have been found practicable in the hospital field and to reduce the risk of related measurements and tests being unnecessarily repeated. All the hospital authorities have been asked to contribute to the series by supplying brief factual details from studies they have undertaken. The second set is made up of six studies. These cover: maintenance of grounds and gardens; document copying; medical stenographers' department; medical records (including mobile steel-shelving and addressing machine systems); and, finally, the collection of swill from hospital wards.

How Old are the Angiosperms?

In the first of two recently published papers a fossil nut which looks very like some of the modern Icacinaceae is described ("An Early Cretaceous (Hanterivian) Angiosperm Fruit from California", by M. E. J. Chandler and D. I. Axelrod; "How Old are the Angiosperms?" by D. I. Axelrod. *Amer. J. Sci.*, 259, 441; 1961). This tropical family is regarded as moderately advanced, and if the fossil (which is classified with great caution) is rightly placed it fits very nicely with the thesis of the second paper. In this, Axelrod defends his well-known idea that the flowering plants arose in the 'uplands' during the late Palæozoic (and being upland were very seldom preserved). Here in the uplands they evolved most of their families during the early Mesozoic, and when they appear in force in the Upper Cretaceous this is due to their conquest of the delta habitat rather than to evolution.

Axelrod's arguments had recently been attacked by Scott, Barghoorn and Leopold ("How Old are the Angiosperms?", *Amer. J. Sci.*, 258, A, 284; 1960), and a good deal of the present paper can be crudely summarized thus: lack of evidence can be explained away (and in several different ways); and if certain early fossils supposed to be Angiosperms have not been strictly proved to be Angiosperms, neither have they been strictly proved not to be Angiosperms. To the reviewer it looks as if at least as much thesis has by now been built on the early fossils as they will support, and what is needed is more support; not perhaps by more early fossils but by fuller knowledge of those we have. If, for example, the fossil nut in the first paper was shown by further knowledge to agree with the Icacinaceae and with them exclusively, we would have a very useful basal fact.

Yorkshire Philosophical Society

The report of the Council of the Yorkshire Philosophical Society for 1960 rightly states that it was an important year for the Society. By a mandate given at a special general meeting in December 1959, an agreement was made with the Corporation of York for it to take over the future maintenance of the Yorkshire Museum, its collections and Gardens. They will be managed by a joint committee, one-third of the members of which will be nominated by the Council of the Society. Founded in 1822, the decision to give the Museum and Gardens to the City after 139 years of an existence entirely supported by members is a historic one and the occasion was marked by appropriate ceremony. It is felt that the community at large will benefit greatly by such a gift, and the Society will be free to develop its separate interests. An unexpected discovery in the excavations in the Garden was an apparently late-fourth-century ditch. It is hoped that further work will shed more light on this last phase of Roman York.

International Business Machines, United Kingdom, Ltd.

International Business Machines, United Kingdom, Ltd., have announced the foundation of three research fellowships, one in each of the years 1961, 1962 and 1963, tenable at any university or university college in the United Kingdom, under a continuing scheme (*IBM Research Fellowships.* Pp. 4. London: IBM United Kingdom, Ltd., 1961). The fellowships, which will carry a salary of not less than £1,000 a year, will be in no way restricted as to subject, and will be of sufficient duration to allow research into major problems to be undertaken. The 1961 fellowship has been awarded to the Department of English and General Linguistics at the University of Edinburgh. The facilities of the full range of installed International Business Machine equipment are also to be made available free of charge for approved academic and humanitarian research of a non-profit-making nature. The terms of this Endowed Research Time scheme are set out in a further booklet (*Endowed Research Time.* Pp. 3. London: IBM United Kingdom, Ltd., 1961).

Research Grants in Radiological Health

In view of the rapid expansion which is forecast in the use of nuclear energy, X-rays and other sources of radiation, a greatly expanded programme for research grants in the field of radiological health has been developed by the U.S. Public Health Service. These grants are offered to support research by individuals, universities, hospitals, laboratories and other public or private institutions in the assessment and control of the effects of man-made and natural radiation on the individual. Research proposals should contribute to the determination of the extent and character of the radiation problem as well as the mechanisms by which radiation produces damage. Information and application forms can be obtained from Dr. Paul F. Hahn, chief of the Office of Extramural Grants, Division of Radiological Health, U.S. Public Health Service, Washington 25, D.C.

American Grants for Nuclear Equipment in Argentina, Brazil and Israel

The United States is to make available to the International Atomic Energy Agency approximately 80,000 dollars-worth of nuclear equipment to assist in developing the peaceful uses of atomic energy in Argentina, Brazil and Israel. Argentina will receive a grant for a mass spectrometer ion-source to be used in the electromagnetic separation of short-lived radioactive material, and an electron paramagnetic resonance spectrometer to be used in connexion with solid-state physics work being conducted at the Institute of Physics of San Carlos de Barilocho. The grant to Brazil will provide equipment for research in the use of isotopes in agriculture. Israel will receive equipment for one mobile and two stationary monitoring stations as part of its radiological protection programme to provide routine monitoring of the area surrounding the swimming-pool-type research reactor located near Rehovoth, Israel.

Monograph Prizes

The American Academy of Arts and Sciences is offering three 1,000-dollar prizes, to be awarded annually to the authors of unpublished monographs —one each in the fields of the (1) humanities, (2) social sciences, (3) physical and biological sciences. The final date in 1961 for receipt of manuscripts by the committee on awards is October 2. Details can be obtained from the Committee on Monograph Prizes, American Academy of Arts and Sciences, Little Hall 33, Harvard University, Cambridge 38, Mass.

NATO Advanced Study Institute Programme, 1962

Short courses at which scientific topics are discussed at an advanced level may be eligible for financial support under the NATO Advanced Study Institute Programme. Courses should last for two weeks or longer, and participants should be drawn from several countries. The NATO grant may be used for administrative expenses, publication of the proceedings, and to subsidize the expenses of foreign visitors. Courses in any of the sciences, for example, mathematics, astronomy, physics, chemistry, biology, etc., are eligible for support. The meetings may consist of experimental classes, as well as the more usual arrangement of lectures and discussions. The Programme, which this year is supporting nineteen courses, will continue in 1962, subject to confirmation from the appropriate authorities. It is hoped to raise the budget-level of the Programme. Persons interested in organizing such courses and requiring financial assistance from NATO should write, before December 1, to the Scientific Affairs Division, NATO, Place du Maréchal de Lattre de Tassigny, Paris 16e, France.

Royal Meteorological Society: Officers for 1961–62

THE following have been elected officers and Council for 1961–62 of the Royal Meteorological Society: *President*, Dr. H. L. Penman; *Vice-Presidents*, Dr. A. G. Forsdyke, P. J. Meade, J. S. Sawyer, Dr. J. M. Stagg; *Vice-President for Canada*, Dr. F. K. Hare; *Vice-President for Scotland*, R. Cranna; *Treasurer*, B. C. V. Oddie; *Secretaries*, Dr. R. C. Frith, Dr. R. S. Scorer, Dr. F. Pasquill (*Editor*), G. A. Bull (*Librarian*); *Ordinary Members of Council*, Dr. J. A. Chalmers, T. J. Chandler, R. H. Clements, J. R. D. Francis, W. A. Grinsted, Dr. J. T. Houghton, E. Knighting, A. L. Maidens, Dr. J. L. Monteith, P. R. Owen, Inst. Capt. R. Thorp, Dr. G. B. Tucker.

University News : Edinburgh

THE following have been made readers within their respective faculties, with effect from October 1: (*a*) Faculty of Medicine, Dr. Eric Samuel, honorary senior lecturer in radiodiagnosis (status of honorary reader), Dr. H. M. Adam, senior lecturer in pharmacology, and Dr. J. S. Robson, senior lecturer in therapeutics; (*b*) Faculty of Science, Dr. N. A. Mitchison, lecturer in zoology.

Appointments have been made as follow: Dr. P. P. Brown, lecturer in bacteriology; Dr. W. P. Doyle and Dr. J. L. Holmes, lecturers in chemistry.

The Department of Radiotherapy has received an anonymous gift of £1,000 for research.

Royal College of Science and Technology, Glasgow

DR. DAVID W. A. SHARP has been appointed senior lecturer, and Dr. Graham R. Knox lecturer, in the Department of Chemistry from September 1.

London

THE following have been appointed readers in the Imperial College of Science and Technology : Dr. C. B. Alcock (chemical metallurgy), Dr. J. N. Hunt (physical oceanography), Dr. J. A. Kitchener (science of mineral processing).

Manchester

MR. R. H. KANTOROWICH, formerly lecturer in town planning in the Department of Land Surveying and Civil Engineering at the University of Cape Town, has been appointed professor of town and country planning in succession to the late Prof. Clifford Holliday.

Southampton

THE following appointments have been made: Mr. B. M. Bland, at present deputy librarian in the University of Birmingham, to the University librarianship; Mr. H. J. Trump, at present director of extramural studies in the University of Glasgow, to the directorship of adult education; Dr. J. P. Jones, senior lecturer in the Department of Aeronautics and Astronautics, to the Westland readership in helicopter engineering. The title of reader has been conferred on Dr. I. G. M. Campbell, senior lecturer in the Department of Chemistry.

Announcements

SIR RUDOLPH PETERS, emeritus professor of biochemistry in the University of Oxford, and Dr. J. L. Pawsey, assistant chief of the Division of Radiophysics, Commonwealth Scientific and Industrial Research Organization, Sydney, have been awarded the degree of Hon. D.Sc. of the Australian National University at Canberra.

MR. DAVID OWEN, assistant head of the Department of Operational Research and Cybernetics of the United Steel Companies, Ltd., has been appointed head of the Department in succession to Mr. Stafford Beer, who is to be managing director of a new international firm of operational research consultants based in London.

DR. B. J. A. BARD, vice-chairman of Dracone Developments, Ltd., has been appointed chairman of the company, in succession to Prof. W. R. Hawthorne, professor of applied thermodynamics in the University of Cambridge, the inventor of the Dracone project, who will continue on the board of the company as technical adviser.

MR. N. G. MCCULLOCH has been appointed an honorary life governor of the Cotton, Silk and Man-made Fibres Research Association, Shirley Institute, Manchester, in recognition of his outstanding services to the Association and the industry. Mr. McCulloch has been intimately associated with the Shirley Institute for more than twenty years and played a leading part in the discussions which led to the recent fusion of the British Cotton Industry Research Association and the British Rayon Research Association.

THE Faraday Society has arranged a general discussion on "The Structure and Properties of Ionic Melts", to be held in the Department of Inorganic and Physical Chemistry, University of Liverpool, during September 5–7. Further information can be obtained from the Secretary, Faraday Society, 6 Gray's Inn Square, London, W.C.1.

AN international conference on plasma physics and controlled nuclear fusion research will be held by the International Atomic Energy Agency at Salzburg, Austria, during September 4–9. It is expected that the conference will show what progress has been achieved since the Second United Nations International Conference on the Peaceful Uses of Atomic Energy, held in Geneva in 1958. The proceedings of the conference will appear in special issues of *Nuclear Fusion: Journal of Plasma Physics and Thermonuclear Fusion*, published by the Agency. Further information can be obtained from the Division of Public Information, I.A.E.A., Vienna I, Kärntnorring 11, until August 31, and afterwards at Europahaus, Salzburg, Austria.

WATER RESOURCES OF THE UNITED STATES

As a result of Senate Resolution No. 48 of the Eighty-sixth Congress of the United States, a Select Committee on National Water Resources was set up in 1959 to study the extent and character of water resources activities required to provide the future quantity and quality of water needed for all segments of the economy in the United States.

Under the vigorous leadership of Senator Robert S. Kerr from Oklahoma, this Committee has now completed its assignment and presented its final report and recommendations to the first session of the Eighty-seventh Congress. The final report was preceded by a series of specialist reports which have been appearing steadily over the past two years. A number of these reports has already been reviewed in *Nature* (187, 562; 1960), and have been marked with an asterisk in the now complete list given here. Many of these reports and also the final recommendations will be of interest to those faced with water problems in the United Kingdom and Commonwealth, as well as elsewhere. A brief outline of the salient points of the new reports and the final recommendations therefore follows.

List of Committee Prints issued by the Select Committee on National Water Resources, U.S. Senate, 1959–60, under the title *Water Resources Activities in the United States*. Obtainable from the Government Printing Office, Washington

(*A*) BACKGROUND

1. *Water Facts and Problems*, U.S. Geological Survey.
*2. *Reviews of National Water Resources during the Past Fifty Years*. Legislature Reference Service, Library of Congress.
*3. *National Water Resources and Problems*, U.S. Geological Survey.
*4. *Surface Water Resources of the United States*, U.S. Geological Survey.
*5. *Population Projections and Economic Assumptions*, Census Bureau and Resources for the Future.
6. *Views and Comments of the States*, State reports on their water resources and problems.

(*B*) PROJECTIONS OF FUTURE NEEDS

*7. *Future Water Requirements for Municipal Use*, Public Health Service.
8. *Future Water Requirements of Principal Water-Using Industries*, Business and Defence Services Administration and Bureau of Mines.
*9. *Pollution Abatement*, Public Health Service.
10. *Electric Power in Relation to the Nation's Water Resources*, Federal Power Commission and others.
11. *Future Needs for Navigation*, Corps of Engineers, U.S. Army.
*12. *Land and Water Potentials and Future Requirements for Water*, Department of Agriculture.
*13. *Estimated Water Requirements for Agricultural Purposes and their Effects on Water Supplies*, Department of Agriculture.
14. *Future Needs for Reclamation in the Western States*, Bureau of Reclamation.
15. *Floods and Flood Control*, Corps of Engineers, U.S. Army.
*16. *Flood Problems and Management in the Tennessee River Basin*, Tennessee Valley Authority.
17. *Water Recreation Needs in the United States*, National Park Service.
18. *Fish and Wildlife and Water Resources*, Fish and Wildlife Service.
*19. *Water Resources of Alaska*, U.S. Department of the Interior.
*20. *Water Resources of Hawaii*, U.S. Department of the Interior.

(*C*) TECHNIQUES FOR MEETING NEEDS

*21. *Evapo-Transpiration Reduction*, Department of the Interior and Department of Agriculture.
*22. *Weather Modification*. Weather Bureau and Dean A. M. Eberle.
*23. *Evaporation Reduction and Seepage Control*, Bureau of Reclamation.
*24. *Water Quality Management*, Public Health Service.
*25. *River Forecasting and Hydrometeorological Analysis*, Weather Bureau.
*26. *Saline Water Conversion*, Office of Saline Water, Department of the Interior.
*27. *Application and Effects of Nuclear Energy*, Atomic Energy Commission.
*28. *Water Resources Research Needs*, Department of Agriculture.
29. *Water Requirements for Pollution Abatement*, Prof. George Reid, University of Oklahoma.
30. *Present and Prospective Means for Improved Re-use of Water*, Abel Wolman Associates.
31. *The Impact of New Techniques on Integrated Multiple-Purpose Water Development*, E. A. Ackerman and Associates.
32. *The Supply and Demand of Water in the United States*, Dr. Nathaniel Wollman, Resources for the Future.

(*D*) HEARINGS OF EVIDENCE

Hearings Held by the Select Committee on National Water Resources and published in 23 parts with index. Pp. 3968. (Washington, 1960.)

(*E*) FINAL REPORT AND RECOMMENDATIONS

Report of the Select Committee on National Water Resources, Report No. 29 of the First Session of the Eighty-seventh Congress, 1961.

Committee Print No. 1 consists of copies of the charts prepared by the U.S. Geological Survey on the occasion of the presentation of an account of the water resources and related problems of the United States at a meeting in July 1959. Much of the material in this report is also covered in Print No. 3, which has already been reviewed.

Committee Print No. 5 contains the population projections and economic assumptions on which the studies for the water resources committee are based. This report is of considerable interest and has wider implications beyond that of the water problem. The first part predicts that the population of the United States will reach between 225 and 278 million by 1980, and between 267 and 431 million by the year 2000. Breakdowns of these projections by States and water resource regions, and between urban and rural areas in each water resource region are given. The report covers projections made by the U.S. Census Bureau, the Committee Staff and 'Resources for the Future', a private organization.

Committee Print No. 6 is a voluminous report detailing the views and comments of each State on the water problem. The replies received from the invitation to submit evidence range from brief letters to elaborate treatises from States where water is an acute problem. Taken as a whole the responses provide a valuable background to the national problem.

Report Nos. 8, 10 and 11 form a natural group dealing with industry, electricity and navigation, respectively. Committee Print No. 8 attempts an assessment of the future water requirements of the principal water-using industries. The 1954 census showed a total use of water of more than 12,000 × 10^9 gal. annually in the primary manufacturing industries, exclusive of electric power generation. The Department of Commerce estimates that the 1954 intake of 7,700 × 10^9 gal. for the iron and steel, chemical, pulp and paper, food and beverage, aluminium and copper industries could rise to 26,500 × 10^9 gal. by 1980 and 61,600 × 10^9 gal. by the year 2000. The Bureau of Mines projects water intake in the mining industries from 1,790 × 10^9 gal. in 1954 to 3,765 × 10^9 gal. in 1980 and 4,770 × 10^9 gal. in the year 2000. Taking all industries exclusive of electric power together, a total need of water of up to 36,500 × 10^9 gal. a year by 1980 and double this amount by the year 2000 is estimated. Committee Print No. 10 deals with the needs of the electric power industry, and it is not surprising to see even more astronomical figures. During 1959 about 26,813 × 10^9

gal. of water were circulated in thermal plants of investor-owned systems. By 1980 these will need 106,409 × 10^9 gal. yearly. To this must be added the needs of nuclear power plants and the rural electrification schemes of the Department of Agriculture. Fortunately, from the point of view of national water supplies, most of this water is needed for cooling purposes, and less than 1 per cent is a consumptive use. The same consideration also applies to hydro-electric developments: the report shows that present hydropower capacity represents between one-quarter and one-third of the actual and economic water-power potential, and that the overall resource limitation on hydro development in the United States is not yet within sight. Committee Print No. 11 details the future needs for inland navigation. This report covers briefly the history of navigation on the inland waterways system of the United States (which extends to some 20,000 miles), gives an inventory of the present system, and discusses possible improvements and extensions thereto in the light of the estimates that freight traffic will double by 1980 and quadruple by the year 2000. The improvement of some 10,041 miles of existing waterways and the creation of some 3,070 new waterways might eventually be needed.

Committee Print No. 14 investigates the future water needs for reclamation in seventeen Western States. These States have had in recent years a more rapid growth in population and economic activity than the United States as a whole, and the trend is likely to continue. The Bureau of Reclamation, which has been responsible for much of this development, was asked, therefore, to report on anticipated future developments of reclamation in the Western States between now and the year 2000, including Federal, State and local projects. In preparing its report, the Bureau has inventoried more than 1,000 projects, of which it estimates that some 800 will be realized by the year 2000, bringing in 17 million acres of newly irrigated land and creating 230,000 family-sized farms for an 'on-farm' population of 800,000. This could support a local non-farm population of 2·4 million and provide food and fibre for 25 million people. The full efficient utilization of water resources in the Western States would require significant changes in existing patterns of use of water. Many involved water exchanges would have to be worked out, the State laws with respect to ground water would need modification, a good deal of research on the hydrological cycle would be necessary and many financial problems would need resolution. Appendixes to the report include maps and charts showing the location and construction costs of the 1,085 projects. This report has proved to be one of the most interesting, stimulating and also challenging accounts of the whole series.

Committee Print No. 15 discusses the flood problems of the United States, tabulates past and expected future flood damage by river basins, presents the historical and legislative background of flood control in the United States, and considers possible solutions for flood problems in the light of the fact that overall flood damage is increasing more rapidly than it has been possible to reduce it by the construction of control works. Three alternative methods of reducing damage exist: (*a*) abandonment or evacuation of flood plains; (*b*) regulation of flood plain use to accommodate the use to the flood hazard; (*c*) provision of works and measures for flood protection or control. The report presents an inventory of works and projects needed to prevent flood damage in the foreseeable future until 1980. These works include more than 64 million acre-feet of flood control storage in reservoirs, 4,300 miles of levees and flood walls, and 5,900 miles of channel improvements.

Committee Prints Nos. 17 and 18 serve as salutary reminders that the water problem is not confined to industrial and agricultural interests. The rapidly rising demand for outdoor recreation by an expanding population with a rising standard of living is considered in Report No. 17. There are few outdoor activities from which water is absent, and the report sets forth recommendations from the National Park Service regarding future water recreation needs. It suggests that some 15 per cent of the oceanic and major inland water shoreline should be acquired, that certain free-flowing streams the recreational value of which outweighs other considerations should be preserved, that water reservoirs should where possible be made multi-purpose, that efforts to combat pollution should be increased. Little consumptive water is involved in the report, which is concerned mainly with the need for conservation of water for recreation. Committee Print No. 18 deals with a rather more specialized aspect of outdoor recreation—that of fish and wild life in relation to water resources. The report points out that the problem of maintaining fish and wild life resources are compounded by the combination of the rapidly increasing population and increase in leisure time together with the gradual and increasing encroachment of man's activities on the habitat available for fish and wild life. It is urged that fish and wild-fowl conservation and development should be considered as a co-equal purpose with other demands on water resources development in the United States.

Committee Print No. 29 on pollution abatement supplements Nos. 9 and 24 previously reviewed. One of the principal requirements for water in the future is for the dilution of effluent resulting from the treatment of municipal sewage and industrial wastes which are disposed of into rivers. Prof. Reid, who with the advice of technical experts from the Public Health Service, developed short-cut methods for estimating dilution water requirements, is largely responsible for report No. 29. The study is limited to the rivers in the 22 water resource regions delineated and excludes the problems of tidal estuaries. Waste loadings that would normally be discharged directly into the sea or large lakes were not considered.

Committee Print No. 30 is an important account of present and prospective means for the re-use of water. As demands for water rise, it becomes increasingly necessary for the public to use second-hand water. With all the indications pointing towards a three-fold increase in water withdrawal by 1980, rising to a six-fold increase by the year 2000, the need for improving techniques of water re-use is obviously urgent. The report indicates that already 70 million of the 117 million people now served by public water systems are re-using water that may have passed through a domestic sewage or industrial waste disposal plant at least once. The report is based on a review of several thousand technical papers: it presents methods of reclaiming water from sewage and industrial wastes, outlines the problems encountered in the re-use of water, goes into considerable detail on the restoration and maintenance of underground water supplies, covers ground water recharge, and reclamation of saline waters.

As a fitting companion to Committee Print No. 30 we find No. 31 dealing with the impact of new techniques on integrated multiple-purpose water development. To meet a situation within this century in which water requirements will cause the United States to go beyond the traditional approaches to water development, the report suggests a new type of approach termed "comprehensive development", which is defined as "the application of integrated multiple-purpose design, planning and management which includes joint consideration of ground and surface water, conservational and other measures for engineering of demand, and the treatment and management of water having a substandard quality". This report has been prepared under the direction of Dr. Edward A. Ackerman.

Finally, in Committee Print No. 32, we find a summary report on the estimated supply and demand for Water in the United States for 1980 and 2000 by "Resources for the Future". The basic projections and information supplied by the Federal agencies for each of the 22 regions into which the contiguous parts of the United States were divided for the purposes of the study has enabled tentative balance sheets of water supply and demand to be drawn up. The report also deals with the basic physical problems of providing the necessary facilities for storage and treatment of water. It shows very clearly the great economic advantages that could follow from the more complete treatment of wastes.

These reports, together with the hearings, occupy some 5,800 pages and provide a most detailed picture of the present practice of use of water in the United States, and of impending problems. The final report of the Select Committee on National Water Resources to the Senate (No. 29 of the Eighth-seventh Congress, First Session) summarizes the findings and gives the Committee's conclusions and recommendations. The need for meeting problems before they arise is stressed, and five major categories of effort are thought desirable so as not to inhibit national or regional economic growth: (*a*) regulating stream-flow through the construction of surface reservoirs and watershed management; (*b*) improving the quality of streams through pollution abatement programmes; (*c*) making better use of underground storage; (*d*) increasing the efficiency with which water is used through the elimination of wasteful practices, improved sewage treatment methods, recirculation, increased irrigation efficiency, and substitution of air for water cooling; (*e*) increasing the natural yield of water by desalting, weather modification, and other artificial means.

The Committee's main recommendations to Congress are accordingly:

(1) The Federal Government, in co-operation with the States, should prepare, and keep up to date, plans for comprehensive water development and management for all major river basins in the United States. The Executive Branch should be requested to submit plans to Congress in January 1962, for undertaking and completing such work in all basins by 1970.

(2) The Federal Government should stimulate more active participation by the States in planning and undertaking water development and management activities by setting up a 10-year programme of grants for water resources planning.

(3) The Federal Government should undertake a co-ordinated scientific research programme on water. This should include both research into ways to increase available supplies and ways to increase efficiency in the use of water. The Executive Branch should be requested to submit a programme of research to Congress in January 1962.

(4) The Federal Government should prepare biennially an assessment of the water-supply demand outlook for each of the water resource regions of the United States. The Executive Branch should be requested to submit a programme of research to Congress in January 1962.

(5) The Federal Government, in co-operation with the States, should encourage efficiency in water development and use, by regulating flood plain use, by studying and anticipating water problems, by anticipating storage needs, by increasing public awareness of water problems and by the provision of public hearings where necessary.

Water is to-day assuming an ever-increasing importance as civilization's needs for water and water-related products and services grow. Areas of the globe that will thrive, or even survive, will be determined by the availability of water resources and their wise use to serve man. Growing communities will need increasingly to organize and conserve these resources. Commendable foresight has been shown in the United States in the efforts being made to provide adequate water supplies for the next generation. Most countries, especially the United Kingdom and many members of the Commonwealth, will find the approach, the reports, the findings and the recommendations of the Senate Select Committee which have been considered here of great value and interest to them in dealing with their own water problems.

W. G. V. BALCHIN

FLORA EUROPÆA

THE second symposium of Flora Europæa was held during May 21–28, 1961, in Italy. It was divided into three parts, the first in Genoa, where five days were devoted to various papers and discussions, the second consisting of an excursion to Viareggio and the Apuane Alps, ending in Florence where the final sessions of the symposium were held in the Botanical Institute.

The meeting was attended by participants from Denmark, Switzerland, Sweden, Finland, Iceland, Poland, Portugal, Spain, Rumania, Germany, Yugoslavia, Belgium, France, Austria, Norway, as well as Italy and by all the members of the British Editorial Committee.

In Genoa the symposium was held in the University Botanical Institute, founded by the British philanthropist and merchant, Thomas Hanbury, whose name the Institute still bears. The Institute is situated high above the city, surrounded by its Botanic Garden, and made a very appropriate and comfortable meeting place. The arrangements were made by Prof. R. E. G. Pichi-Sermolli, director of the

Institute, with the co-operation of the University authorities.

The keynote of the meeting was international co-operation in European taxonomy, an appropriate theme for the Flora Europæa organization.

The opening session on Sunday morning included speeches of welcome by Prof. Pichi-Sermolli and University dignitaries, to which Prof. T. G. Tutin (Leicester, chairman of the Editorial Committee) replied in English and Prof. D. A. Webb (Dublin) in Italian. In the afternoon Prof. Tutin outlined the progress made by the Flora Europæa organization since the last meeting in Vienna. He recalled how the Editorial Committee had received a substantial grant from the Department of Scientific and Industrial Research, which enabled the secretariat to be established on a permanent basis and allowed the employment of two research assistants. The circulation of manuscripts of Volume 1 to the regional advisers had proceeded successfully during the past two years, and he discussed the three main points that had been raised by the advisers. These were distributional, ecological and cytological data. There had been great insistence on the importance of giving as detailed ecological information as possible, but in the discussion that followed Prof. Tutin's paper it was made quite clear that although some species have a fairly consistent general ecology there are many which show surprising exceptions or unexpected variation. None the less some advisers, such as Prof. R. Nordhagen (Oslo), felt that even such elementary information as whether a species grew in wet or dry habitats should be given. Prof. W. Lüdi (Zurich) suggested that certain generalized information could be given by using categorized types of ecological preferences which would be useful for non-taxonomists. It was eventually agreed that authors of accounts should attempt to summarize the ecological characteristics of the species in the manuscripts circulated to the regional advisers and these could then be criticized by them.

Dr. V. H. Heywood (Liverpool, secretary of the Editorial Committee) then gave a brief report on the state of preparation of Volume 1 of the *Flora*. The first manuscripts were sent out to regional advisers in December 1958. Since then 150 have been circulated and a further 50 have been prepared and are being revised by the Editorial Committee prior to circulation. Approximately two-thirds of the first volume have been completed and manuscripts of the remaining third are in active preparation. Furthermore, several authors are preparing accounts for the second volume and some have already been submitted. Since the Vienna meeting a supplement to the Green Book (*Guide to Contributors*) had been published[1], the Vienna Symposium report had appeared as a number of *Feddes Repertorium*[2] and the first of the *Flora Europæa Notulæ Systematicæ* were in the press[3].

The second day of the meeting was devoted to a consideration of post-war European taxonomic and floristic literature. Regional advisers were asked before the meeting to prepare reports on the situation in their countries, together with a bibliographical list of the more important papers published since 1945. Reports from 16 countries were received and duplicated copies were distributed to participants as a volume of some 250 pages.

Dr. Heywood gave an introductory analysis of these floristic reports, making the following points: It was interesting to note how frequently it was mentioned that taxonomic and floristic studies had been neglected in several countries since the War for one reason or another. Equally interesting were the reasons for renewal of activity in many cases. For example, phytosociological or topographic-distributional investigations (often undertaken for economic reasons) have given an impetus for much floristic work. There were dangers, however, attendant on this since it often involved cursory identification in the field subject to considerable errors. It was in fact true of certain regions that the only floristic information available had to be drawn from phytosociological lists. Another noteworthy feature was the lack of modern Floras in the Mediterranean region, precisely those areas with the greatest floristic diversity. In more northern countries the tendency was towards biosystematic studies. An unfortunate feature was the small number of monographs or revisions that were being prepared, a tendency which fits in with the world pattern.

The number of journals in which European taxonomic and floristic literature is published is about 500, which in itself presents problems, since few institutions regularly receive more than a proportion of them. As a result there is often considerable ignorance as to the activities of other taxonomists, with consequent duplication of effort in some cases. The solution to this kind of problem lies very largely in improving abstracting services, a subject which was discussed later. It was encouraging to note that several European journals or organizations already produce some sort of annual listing of relevant literature published in their country. Prof. Böcher (Copenhagen) suggested that it would be of great service to taxonomy if these annual reports could be united and circulated together. It was agreed to investigate the possibilities of doing this.

Brief surveys of post-war taxonomic activity were then given by Prof. T. W. Böcher (Copenhagen, for Denmark), Prof. F. Markgraf (Zürich, for Albania), Prof. R. Nordhagen (Oslo, for Norway), Dr. A. Lawalrée (Brussels, for Belgium), Prof. A. Borza (Cluj, for Rumania), Prof. K. H. Rechinger (Vienna, for Austria and Greece), Dr. N. Hylander (Uppsala, for Sweden), Prof. R. E. G. Pichi-Sermolli (Genoa, for Italy), Dr. S. M. Walters (Cambridge, for Great Britain), Prof. D. A. Webb (Dublin, for Ireland), Prof. B. Pawlowski (Cracow, for Poland), Prof. W. Lüdi (Zürich, for Switzerland), Dr. A. Löve (Montreal, for Iceland), Dr. Pinto da Silva (Sacavém, for Portugal), Prof. A. R. Merxmüller (Munich, for West Germany), Prof. W. Rothmaler (Griefswald, for East Germany), Prof. E. Guinea (Madrid, for Spain), Dr. P. Jovet (Paris, for France), and Prof. E. Mayer (Ljubljana, for Yugoslavia).

It is intended to publish revised versions of all these floristic reports in a special number of the journal *Webbia* in 1962.

On May 23, two papers were given on the Italian flora. Dr. G. Moggi (Florence) gave a survey of the state of floristic investigation in the southern half of Italy and in Sicily. It was a revelation to most participants to learn just how poorly large areas of southern Italy had been studied floristically, and it is hoped that Dr. Moggi's map illustrating this will be published with his paper as part of the *Proceedings of the Symposium*. The second paper was by Dr. S. Pignatti (Padua) on the taxonomy and relationship of the genus *Limonium* in Italy and Spain. This was followed by a lively discussion.

The following morning was devoted to considering the problems of abstracting and indexing European taxonomic literature. Dr. S. M. Walters (Cambridge) surveyed the major schemes of indexing and abstracting already in existence, such as the *Index Kewensis, Excerpta Botanica,* and national ones such as the *Plant Breeding Abstracts* published by the Commonwealth Bureau of Plant Breeding and Genetics, Cambridge, and certain private systems. All these have certain limitations such as incompleteness. The second question to be considered was how far they overlapped one another, and the third aspect covered was a consideration of how these facilities could be improved and modified. During the discussion attention was directed to several other abstracting systems that existed, and the regional advisers agreed to submit information on these to the Flora Europæa secretariat. The combined information would then be circulated.

A more long-term possibility of improving the abstracting facilities was discussed by Mr. S. Gould (Connecticut) who attended the meeting as an observer. He is working with a grant from the U.S. National Science Foundation, towards the setting up of an International Plant Index. The details of his methods, which involve the use of a punched card system, were explained and keenly discussed, and many participants agreed that the International Plant Index might form a useful basis which could be utilized for indexing European taxonomic literature. The possibilities of co-ordination would be further investigated and it was hoped that Mr. Gould's scheme would be successfully continued.

The next paper was by Dr. E. Weinert (Halle), who gave, on behalf of Prof. H. Meusel (Halle), who was unable to attend, examples of methods of indicating extra-European distributions for species in the text of *Flora Europœa.* The general principles employed in the examples were accepted, and Dr. Weinert said that the staff of Prof. Meusel's Institute would supply the necessary information for the whole of Volume 1, details in critical cases to be arranged with the authors of the accounts.

A problem related to the use of European taxonomic literature was reported on by Prof. D. A. Webb, who outlined progress that had been made in the preparation of a *Lexicon Polyglottum.* This was essentially a Latin-based list of about 200 terms commonly used in Floras with the equivalents in most European languages. A number of partial lists had already been prepared for immediate use and these had revealed a number of unexpected problems. It was, for example, impossible to find equivalents for certain terms in some languages. Also, terms may be used in different senses in some countries so that considerable problems of interpretation arise in producing the glossary.

The question of terminology was then discussed further by Prof. N. A. Burges (Liverpool), who outlined the problems he had come across in attempts to introduce some sort of standardization of terminology in the manuscripts of the first volume of the *Flora.* As might be expected, this generated a lively controversy over the use and application of technical terms. What several participants regarded as loose British usage of the term 'fruit' came in for considerable criticism and several minutes were devoted to discussing how the fruiting structures of *Ranunculus* and similar genera should be described. The discussion had to be terminated before it extended to detailed consideration of the whole botanical vocabulary. Prof. Burges suggested that the number of complicated terms used was to some extent correlated with the age and experience of the writers of the manuscripts, although there were exceptions, but this provocative issue was not pursued !

Alien plants was the first subject for discussion on May 25. Prof. Webb recalled the various suggestions that had been made at the Vienna Symposium concerning the treatment of aliens, notably by Dr. Hylander (Uppsala) and Prof. Jalas (Helsinki), and outlined the decisions made by the Editorial Committee. Several of the proposals, such as the distinction of casual species by a special sign, had been rejected on the grounds that the number of species involved would be too large, to say nothing of the difficulties of obtaining the necessary information. Similarly the proposal to include archæosynanthropes with native plants and the designation of only neosynanthropes as alien was rejected on the grounds of impracticability. Other proposals were however accepted, such as the inclusion of well-established aliens even if found only in one small district. Prof. Webb then went on to consider the terminology to be applied since there was considerable confusion in the literature. The term 'adventive', for example, is used in various senses. The terms proposed for use in *Flora Europœa* were: (1) cultivated or planted; (2) wild ; (3) native ; (4) alien; (5) established; (or naturalized) alien; (6) casual. Definitions of these were given, and regional advisers were invited to submit agreed equivalents in their own languages. Criteria for the inclusion of aliens in *Flora Europœa* were then discussed. Prof. Webb concluded with a call for information about: (*a*) botanists who take a special interest in alien plants and who could assist in assessing information about them according to the criteria agreed on ; (*b*) literature references published since the appearance of the standard Flora of the country. This information was particularly urgent for a number of countries such as Albania, Corsica, Greece, Spain, Sardinia, Turkey-in-Europe, none of which possesses an adequate Flora less than twenty years old.

The next subject for discussion was again introduced by Prof. Webb. It concerned the need for the preparation of regional check-lists for *Flora Europœa.* In a number of regions the information available in existing Floras was not sufficient to establish the presence even of non-critical species. The compilation of lists for certain regions such as Albania (P. W. Ball, Liverpool), Turkey-in-Europe (D. A. Webb, Dublin), Spain (V. H. Heywood, Liverpool) was now in hand, but lists for such areas as Greek Macedonia and Thrace, and Yugoslav Macedonia were urgently needed. Another such area was Sardinia, and Prof. Pichi-Sermolli thought that it might be possible to organize a list.

The final session in Genoa was devoted to a consideration of hybrids in *Flora Europœa,* and the main paper was given by Prof. D. H. Valentine (Durham) who, after a theoretical introduction, surveyed the type of problems arising in genera such as *Rumex, Salix* and *Saxifraga* which occur in the first volume of the *Flora.* No major departure from the rules set out in the *Guide to Contributors* was proposed, although there were proposals for greater consistency in the designation of hybrids by formulæ and binomials.

In the discussion attention was directed to the necessity for careful investigation in groups where hybridization was known, since the hybrids often resembled one of the parents so closely that they were not detected. The question of intergeneric hybrids was also discussed, particularly with reference to the Gramineae.

In Genoa both the University and the city authorities provided generous hospitality. A reception was held at the Palazzo Tursi by the Mayor of Genoa, and the participants had an opportunity of examining there some of the original correspondence of Christopher Columbus. An extensive tour of Genoa and the Riviera de Levante, including Santa Margherita Ligure and Portofino, was provided by the Tourist Organization. The meeting in Genoa ended with a banquet given by the University at Boccadasse. The festivity of this occasion was enhanced by several speeches, including one by Prof. A. Borza in Latin which received an ovation. Prof. Borza, the doyen of the botanists present, took the opportunity of announcing two new species he had discovered—*Tutinia gravis* and *Heywoodia agilis*. Since the eloquent Latin descriptions he gave were only verbal and were not therefore effectively published according to the *International Code of Nomenclature*, steps are being taken to remedy this through other channels.

The next two days were spent on a profitable and enjoyable field excursion—on May 26 to the nature reserve of Portofino, Passo del Bracco and the celebrated *Pinus pinea* forest at Migliarino, spending the night at Viareggio. On May 27 the excursion went inland to the marble mountains of the Apuane Alps, climbing to the peak of Monte Altissimo. Florence was reached by evening and the final sessions of the symposium were held the next day, May 28, in the Botanical Institute of the University. In the morning members were shown around the various sections of the Institute, including the newly constructed phytotron and the elegant and spacious herbaria and library. A reception was held in the library dominated by the bust of Philip Barker Webb, whose herbarium, together with the other major collections, make Florence one of the most important centres for taxonomic botany in Europe.

The closing session of the symposium was held in the afternoon when the main business was the report of the Nomenclature Sub-committee, given by the chairman, Dr. N. Hylander. Most of the discussion centred round the validity of publication of the species contained in such works as Gandoger's *Flora Europae*. It was decided to make further studies and arrive at an assessment of the number of species involved and the number of changes of name which they might cause before reaching a decision. It was also agreed to circulate lists of *nomina ambigua* to the members of Flora Europæa with the view of reaching agreement on which of these names should be rejected.

The meeting ended with speeches by Prof. Pichi-Sermolli and Prof. Lüdi. Prof. Borza expressed the hope that it would be possible to hold the next meeting in Rumania. The second Flora Europæa symposium was thus successfully concluded, and co-operation for the future firmly established.

EUROPEAN BROADCASTING CONFERENCE, STOCKHOLM

During May 26–June 23, a European conference on "Broadcasting" was held in Stockholm under the auspices of the International Telecommunication Union. The objects of the conference were: first, to revise the 1952 Agreement reached also at Stockholm for the use of the very high-frequency Bands I, II and III for sound and television broadcasting; and secondly, to prepare plans for the future development in the European area of sound broadcasting in Band II, and of television in the ultra-high frequency Bands IV and V. This year the conference was attended by delegates from some forty national administrations, and by representatives of a number of international organizations.

The conference was opened by Dr. Hakan Sterky, director-general of Swedish Telecommunications; and at the first meeting, Dr. E. Esping, technical director of Swedish Telecommunications, was appointed chairman, assisted as vice-chairmen by Captain C. F. Booth and Mr. A. Badalov, leaders of the United Kingdom and U.S.S.R. delegations, respectively.

The technical basis for this recent conference had been formulated in March at a meeting of technical experts of the International Radio Consultative Committee held in Cannes. A detailed report of this meeting provided full information on technical matters, such as the characteristics of transmitters and antenna systems, propagation curves for land and sea conditions, and the signal protection ratios requisite for satisfactory reception of television in the ultra-high-frequency bands from 470 Mc./s. upwards.

The final report adopted by the recent conference at Stockholm will await endorsement by the various national administrations represented. It contains full details of the stations proposed for sound and television broadcasting in the future. In particular, some five thousand stations are listed in the ultra-high-frequency Bands IV and V, together with the frequencies assigned to these stations to avoid mutual interference during operation. A uniform channel-width of 8 Mc./s. was proposed for each station, consistent with the adoption of the 625-line standard for the vision signals. In view of the rapid development of television throughout the world at the present time, it was very opportune that this conference was held so that satisfactory plans could be made on a sound technical basis.

One of the participating bodies at Stockholm was the Inter-Union Committee for the Allocation of Frequencies for Radioastronomy and Space Science, which was established by the International Council of Scientific Unions last year. This committee was represented by Drs. H. Sterky, and J. H. D. von der Toorn, by Prof. B. Linblad, and by Dr. R. L. Smith-Rose, secretary-general of the Committee; and it put forward two recommendations designed to protect observations made by radio astronomers in certain frequency bands. One of these sought to secure the free use of the band 606–614 Mc./s. for the radio astronomy service, and was received very sympathetically by the delegates present at Stockholm, who in a majority of cases agreed to avoid, so far as is practicable, the use of this band for television broadcasting. The second recommendation pointed out the danger of harmonics from certain broadcasting stations in Bands IV and V interfering with radio astronomy observations in the hydrogen band 1,400–1,427 Mc./s. which, in the existing International Radio Regulations, is allocated exclusively for the radioastronomy service. It was recommended that administrations should take all practicable precautions to avoid such interference.

THE BRITISH ELECTRICAL AND ALLIED INDUSTRIES RESEARCH ASSOCIATION

THE annual report of the British Electrical and Allied Industries Research Association opens with a reference to the fact that it records the work of the Association's fortieth year.

Of the work started by the Association in its early days which has contributed substantially to the development of the electrical industry may be mentioned, particularly, research on insulation, on circuit breaking and switchgear, and on the loading capacity of cables. These branches of work still feature largely in the Association's activities.

It was in the third year of the Association's existence that electricity supply undertakings, joining as associate members, initiated the co-operation in research between manufacturers and supply authorities which has continued ever since. Work which is of vital importance to the supply industry and which has been pursued continuously for many years is the determination of the properties of steam at high temperatures and of the characteristics of steel in relation to withstanding high temperatures and stresses.

The present major classifications of the Association's research activities are as follows: insulation and dielectrics; switch and control gear; power plant; insulated cables; overhead lines; surge phenomena; integrating meters; magnetic materials; transformers; flame-proofness and intrinsic safety; earthing; safety and circuit problems; rural electrification; heating, cooking and allied problems; electric equipment of automotive systems and communication interference. In addition, there is a small miscellaneous group designated "Unclassified Researches".

The more important results obtained during the year in these various fields, summarized in individual paragraphs of the report, comprise for the most part technological information which is applicable directly in the electrical industry, but there is in addition a substantial volume of new scientific knowledge.

An investigation of the resistance of industrial insulating materials to surface discharges, a phenomenon known as 'tracking', has shown that the resistance to tracking of a poor material is not increased greatly by a substantial increase in the creepage distance.

Measurements relating the temperature of buried cables to seasonal variations of soil properties have been made, and the possible advantages of using special 'backfills' for cable trenches are being investigated.

In relation to flame-proof equipment it has been shown that for some explosive gases obstructions in close proximity to, but *outside*, the flange gap increase the hazard of explosion, a wrapping of tape to improve dust tightness being particularly dangerous.

Following an investigation of the characteristics of electrical floor-heating for buildings, recommendations have been issued and are now being adopted.

It is also noted that interesting records were obtained last year of the behaviour of the heating system installed for frost protection under the road surface at the Mound in Edinburgh.

Work on vacuum circuit breakers, switches and contactors continues, and it is reported that the vacuum contactor has now reached the stage of commercial development.

In relation to interference arising from industrial radio-frequency equipment, it is stated that all the information has been obtained which is necessary for the preparation of statutory regulations.

In the field of agriculture, reference is made to investigations into methods of drying grain. It appears that for continuous-flow drying the most suitable electrical technique will be infra-red heating.

Among the fundamental researches conducted in university departments under the ægis of the British Electrical and Allied Industries Research Association may be mentioned the work carried on in Liverpool on the theory of conduction in semi-conductors. It is known that the conductivity of germanium increases by several orders of magnitude at fields of 2 V./cm. and at liquid helium temperature. This phenomenon, which is often termed 'breakdown', has been shown to be quite unconnected either with instability or with destruction of the lattice. It can, in fact, be predicted theoretically on the basis of earlier work on 'hot' electrons.

Work on gas-discharge phenomena is also in progress with the Townsend ionization chamber on the measurement of ionization and attachment coefficients, and a comprehensive range of data has been obtained for carbon monoxide.

The velocity distribution of cathode particles originating from the spot of a low-current arc between copper electrodes *in vacuo* has been investigated at Oxford.

At the University of Durham experiments are in progress on collision ionization at ultra-high frequencies.

Perhaps the most noteworthy illustration of the traditional freedom of scientific inquiry occurs under the heading "Astrophysics" in the section of unclassified research work.

Originating in the important technological investigation of arc phenomena in circuit breaking, there has developed the idea of applying fundamental electrical discharge theory to problems on the macroscopic scale of astrophysics. Since 1944 several papers dealing with the development of these hypotheses have been published.

During the past year, observations have become available from astrophysical and space research which confirm predictions of this general theory in some detail.

The application of electrical discharge theory to explain a well-known type of stellar spectrum suggested the existence of spiral nebulæ on a stellar scale. Photographic evidence of the existence of such nebulæ has become available. The theory explains the general form of the planetary nebulæ and of the gas movements observed in them.

Evidence in support of another prediction has resulted from satellite observations by U.S. naval scientists. The observations of 80,000-V. X-rays associated with solar flares implies the existence of temperatures of about 100,000,000° K. in solar atmospheric electrical discharges. The prediction that such temperatures must exist in this region was made from electrical discharge theory applied to magnetic storms.

Another interesting by-product of theoretical work in a different field is a new method of measuring the surface tension of a clean surface in a liquid. This results from the mathematical solution of the problem of the equilibrium shapes of bubbles in electrical and centrifugal fields which was required in a study of the electrical breakdown of liquids, itself part of an investigation on breakdown of highly stressed impregnated dielectrics.

The most notable addition, during the year, to the Association's experimental resources has been the building and equipping of a Creep Testing Laboratory, intended to accelerate the important investigations on the creep behaviour of steels for use at temperatures above 1,050° F. (565° C.).

At the end of the year under review a major reorganization of the Association's committee structure was put into effect. Six divisional committees now guide and superintend the Association's work, replacing twenty-two sectional committees and eighty-one research committees.

An interesting reference is made to the desirability of fostering still closer relations between the Association and the universities and technical colleges. Through its extra-mural programmes the Association already maintains close contact with quite a number of departments in universities and technical colleges. To supplement this, special facilities were instituted to provide for all universities and technical colleges in the Commonwealth obtaining the published reports of the Association. A further step has now been taken in the development of this policy in that professors of electrical engineering and heads of electrical engineering departments in technical colleges have been invited to apply for associateship of the British Electrical and Allied Industries Research Association with full membership benefits.

J. Greig

FOUR DECADES OF STATE FORESTRY IN NEW ZEALAND

The annual report of the Director of Forestry in New Zealand for the year ended March 31, 1960, made to Sir Ernera Tirikatene, the Minister of Forests, is full of interest*. Essentially it consists of 37 appendixes in tabular form, from which progress towards various objectives can be measured, if desired. This will be the last report made by Mr. Entrican, who has just retired after long service.

The report is refreshing for its frankness on some of the mistakes made in the past. It does not disguise the difficulties encountered in the somewhat erratic progress being made towards the building up of a sound forestry practice and the creation of areas of managed forest which are expected to make important contributions to the national economy.

The State service is organized into a number of divisions which deal with management, public and private forestry, development, which comprises training and research, protection forestry, engineering work, operations, industrial operations and, finally, commercial operations.

In the past no more than lip service has been paid to the fundamental principle in forestry of sustaining the yield, and in this report we have a plain confession of neglect to adhere to that principle. "Thus", it says, "on a 2,000-acre area to be managed on a 40-year rotation, 50 acres would be planted annually, with the first 50 acres coming to maturity . . . in the forty-first year, concurrently with the completion of planting over the whole area." New Zealand speaks thus from bitter experience. The Murupara working circle in the largest planted forest there—Kaingaroa—covers 200,000 acres, the oldest portion of which is 37–47 years of age and extends to 10,000 acres only. The next age-class —27–37 years old—covers no less than 150,000 acres, the remaining 40,000 acres being of younger ages. This vast mass of 150,000 acres, composed mainly of Monterey pine (*Pinus radiata* D. Don) is described as "steadily moving towards maturity *en masse*". For various reasons it has been found impossible to cope with the tending of this large area and, in respect of other species in which there are fewer natural deaths, the growing-stock is said to be "accumulating towards stagnation". Here there is a lesson for other countries engaging in large-scale afforestation on fertile land.

New Zealand is anxiously trying to find an outlet for what is frankly called its second-grade timber as a pulp-wood, having produced an excess of certain assortments. An export trade to Australia has been established, but New Zealand openly looks ahead to supplying pulp and paper wood to the rapidly developing populations of the Asiatic countries. A strong plea is made for increasing the area of plantations of exotic conifers, even on good farming land, to produce timber for export, and it is the producer of not enough butter-fat per acre—not of mutton and wool—that is being urged to switch over to forestry. Farmers are asked to plant trees extensively, even to the extent of providing one out of the three million acres of the prescribed afforestation programme, which is expected to increase the area of planted exotic trees to 3,000,000 acres by the year 2025.

Unlike Great Britain, New Zealand still has a large area of indigenous forest. In 1840 the area there covered by these must have amounted to about two-thirds of that of the whole country. Since then they have been considerably reduced. Their treatment has followed the usual Anglo-Saxon pattern of unplanned clearance for farming and of devastation, and exploitation goes steadily on. At one time no thought was given to its conservation as forest, and various arguments were put forward which contributed towards its neglect. Impossibility of regenerating some of the species was one which is now being proved to be without foundation. The main contributing factor was probably the ease and assumed success with which the early exotic plantations were begun. Ironically, one authority has said recently that "the indigenous forest will serve to tide over any crisis arising out of the destruction of the exotic plantations by widespread epidemics of insects and disease".

---

* New Zealand. Report of the Director of Forestry for the year ended 31 March, 1960. Pp. 115. (Wellington: Government Printer, 1960).

Immense areas of the natural forests on the mountainous watersheds of the major rivers have been devastated. Browsing by animals in these areas leads to loss of tree cover followed by erosion and devastating flooding in the rich settled lowland country. In a vast area of more than two million acres of ratakamaki protection forest in the South Island, disastrous results of browsing by opossums, deer and chamois are predicted. In the Waimakariri River catchment area sheep are "slowly making a desert land by close cropping of vegetative cover and exposing the soil to erosion", and threatening the city of Christchurch with possible catastrophe by floods.

The division of protection forestry of the service is responsible for the control of noxious animals, on which nearly £312,000 was spent during the year. In official operations during the year 31,494 deer, 24,830 goats and 4,920 chamois were killed and it is claimed that a bounty was paid in respect of 1,106,000 opossums destroyed.

Not all the new exotic plantations have been made on deep volcanic soils. In one forest in South Island an area of 3,500 acres was blown over by wind on a shallow soil, where, owing to rooting difficulties, the trees appear to be unable to stand after reaching a height of 50 ft. This sort of thing is also very liable to happen in Great Britain.

The New Zealand report faces up to another forestry problem, namely, that of putting timber grown in remote areas on the market. The costs have been found to be so high that they are used as a strong argument that farmers and others should grow trees nearer centres of consumption and should exploit and convert them there. This runs counter, however, to any policy which seeks to establish, or maintain, a healthy rural population.

The future of forestry in New Zealand is looking more hopeful for two main reasons. The first is that forest management, though still very backward when compared with some European countries, is being given more attention. Management plans, which are "forest regulations prescribing the application of certain sylvicultural rules, and the execution of certain works to produce a definite result", now apply to no less than 3,080,000 acres of the indigenous forest. The definition of the objects for which each forest is to be managed is a matter of vital importance and the progress made recently is heartening.

The second reason is that great stress is at last being laid on the need for research in forestry. There is now a large staff of workers so engaged, and the Forest Research Institute at Rotorua publishes its own report, which is rather voluminous, and describes work on a wide variety of subjects. It is gratifying to see that attention since 1956 has been directed to the study of the indigenous forest, which may be a dangerous concept, but is a very significant reality in New Zealand, from which very important lessons can be learnt.

THE CASE FOR A NEW PROFESSION EMBRACING SCIENCE, LIBRARIANSHIP AND FOREIGN LANGUAGES

A SURVEY*, supported by the National Science Foundation and sponsored by the Modern Language Association of America, and carried out under sub-contract with the latter Association as part of a contract with the United States Office of Education, Department of Health, Education and Welfare, argues the case for a new profession concerned with the handling of scientific information, librarianship and foreign languages. Its six chapters delineate first the characteristics of this new profession and the influences which have determined its emergence; the snares and problems of recruitment; undergraduate and graduate education in relation to the supply of such recruits; professional training; and the nature of the professional support which is required, in which connexion the authors recommend establishment of an advisory board to devise an appropriate well co-ordinated programme of courses, seminars, research groups or short-time institutes for training those already engaged in the profession or proposing to enter it. There are numerous detailed recommendations, many of which are applicable in Great Britain also, but although Messrs. L. Cohen and K. Craven lean towards the formation of a professional body, they are not explicit on the point and do not recognize the difficulties inherent in the presence of corporate bodies and individual practitioners which have, in Great Britain, considerably hindered the development of a really strong and representative professional qualifying body.

Some of the recommendations are directed towards management, for example, those relating to salary structure, status and standards. The contribution of the scientist is recognized in recommendations relating to co-operation and mutual understanding between scientists as such and those engaged in information work. Recommendations relating to undergraduate facilities stress the importance of at least two foreign languages, a broad liberal arts education and a major course in a scientific discipline for those entering on scientific information work. Establishment of a graduate school of science information leading to a master's degree is recommended as well as research leading to the establishment of a doctoral programme in this field and the growth of specialized information centres at the universities. They also recommended that technical institutions should explore the needs of industry and government for technicians in special libraries and science information centres and offer appropriate curricula, covering such subjects as machine searching, operation of related communication and retrieval instruments, routine indexing and coding tasks.

---

* Science Information Personnel: The New Profession of Information Combining Science, Librarianship and Foreign Language. By Leonard Cohen and Kenneth Craven. Pp. vi+74. (New York: Science Information, P.O. Box 624, Radio City Station, 1961.) 1.50 dollars.

While the survey anticipates recognition of a more systematic and integrated approach to the organization of scientific information and the according of professional status to the scientific information specialist, the practical difficulties which the implementation of its recommendations are likely to encounter, for example, in regard to teaching staff, at least in the United Kingdom, are scarcely faced. There is also much preliminary work to be done by those already working as information officers and librarians in this field before an appropriate professional body could be formed. Nevertheless, much already exists to form the basis, and the development of the National Lending Library for Science and Technology and of the National Reference Library of Science and Information should stimulate the support and organization of research experiment and development into the nature and techniques of communication, the information requirements of scientists, the nature of technical literature sources, manual and mechanical information systems and devices, and the organization and dynamics of information facilities, which the authors of this survey both urge and expect.

DISTRIBUTION OF BRIGHTNESS IN EXTRAGALACTIC RADIO SOURCES

By A. T. MOFFET and P. MALTBY

California Institute of Technology, Pasadena

As part of a continuing programme of angular size and brightness distribution measurements, we have observed 180 radio sources with the variable spacing interferometer at the Owens Valley Radio Observatory. In this article we report our results for a group of 88 sources which have been observed with both an east–west and a north–south baseline. All observations were made at a wave-length of 31·3 cm. Some preliminary results of the east–west observations were reported by Bolton[1].

The instrument has been described by Read[2], and consists of two equatorially mounted 90-ft. paraboloids, which can be moved along railroad tracks to certain fixed observing stations. When these observations were taken, there were stations at spacings of 200 ft., 400 ft., 800 ft. and 1,600 ft. east and north of a central junction. With one antenna at the central junction and the other at each of these stations successively, a primary set of observations was made, at transit, of the apparent intensities and positions of the sources. From these observations the amplitude and phase of the complex visibility function[3] for each source in the east–west and north–south directions were deduced. A secondary set of intensity measurements was taken off the meridian at each spacing in order to obtain supplementary information about the behaviour of the visibility function at other spacings or directions. The distribution of brightness of a source is related to its visibility function by a Fourier transformation[3]. The primary observations may be considered to be somewhat the same as observing the source with two fan beams, each having dimensions of about 2 × 50 min. of arc.

With a maximum antenna spacing of 1,557 wavelengths, we were able to distinguish details of source structure larger than about 1·5′. For a source with diameter between 0·6′ and 1·5′, an estimate of the diameter was possible, and this was taken to be the width at half-brightness of the circular Gaussian model which fitted best the observed visibility function. The structure of a larger source was determined by comparing the observed portion of the visibility function with artificial visibility functions, calculated for a number of physically reasonable models.

It was found that the majority of the sources greater than 1·5′ in extent could not be interpreted as simple, symmetrical sources in which the brightness decreased monotonically from a single peak. About 10 per cent of all the sources were found to fit a model with two equal centres of emission. Of these, Cygnus *A* is the classic example. These sources are listed in Table 1.

Table 1. Sources consisting of Two Equal Components

3*C*-75
3*C*-111
3*C*-134
3*C*-219
3*C*-270
NGC 5128 (centre source)
3*C*-310
Cygnus *A*
3*C*-445

The results of the interpretation are shown in Table 2. About half the well-resolved sources were asymmetrical and could be interpreted either as consisting of two unequal components or as single asymmetrical distributions. Comparing the east–west and north–south observations, we found that these sources were usually quite elongated, with a ratio of major to minor axes of ⩾ 2 : 1. The remaining one hundred sources, which we have observed only along one baseline, seem to be distributed among the various classifications in more or less the same proportions as those reported in Table 2.

Table 2. Numbers of Sources of Different Types. Diameters refer to a Circular Gaussian Model

Interpretation	No. of sources
Two equal components	9
Halo + core	4
Asymmetrical or two unequal components	26
Diameter between 1·2′ and 2·5′ in one direction; most are elongated ⩾ 2 : 1	10
Diameter < 1·2′	39

We suggest that many of the asymmetrical sources really consist of two unequal components. To obtain further proof of this, it will be necessary to take observations with a smaller effective beam-width than that used in this work. At large antenna spacings, the visibility function of a source with two well-separated, unequal components will differ markedly from that of a source with a single asymmetrical distribution of brightness. Long baseline observations made at Jodrell Bank[4] tend to support our suggestion.

We have considered the possibility that the double radio sources may be connected with double, interacting galaxies, as is the case in Cygnus *A*. A number of identifications of radio sources with optical objects has been reported[1,5,6]. Comparing these results with our own, we find that there is not a clear correlation between double radio sources and double galaxies.

We have suggested that the majority of the discrete radio sources are double, physically linked radio systems; however, it will be necessary to have more identifications with optical objects before conclusions can be drawn about the physical mechanism responsible for this phenomenon.

Details of this work will be published elsewhere. The programme of research in radio astronomy at the California Institute of Technology is supported by the United States Office of Naval Research. One of us (A. T. M.) has held a National Science Foundation pre-doctoral fellowship during the course of this work. The other (P. M.) has a Fulbright travel grant and a grant from the Norwegian Research Council for science and the humanities.

COMPARISON OF BERYLLIUM-7 AND CÆSIUM-137 RADIOACTIVITY IN GROUND-LEVEL AIR

By DR. P. F. GUSTAFSON, M. A. KERRIGAN and S. S. BRAR

Division of Biological and Medical Research, Argonne National Laboratory, Argonne, Illinois

SINCE the discovery of carbon-14 produced by cosmic rays by Anderson and Libby in 1947 [1], a number of other radionuclides, also produced by cosmic-ray interactions with atmospheric constituents, have been found in the atmosphere and in the oceans. Several investigators, notably Lal[2] and Peters[3], have suggested that these naturally occurring radionuclides might prove useful in the study of atmospheric mixing and circulation. For this purpose, beryllium-7, first reported by Arnold and Al-Salih in 1956 [4], is probably the most important. The rate of production of beryllium-7 is exceeded only by that of carbon-14 and tritium. The high specific activity resulting from its 53-day half-life and the lack of dilution by stable beryllium make it an attractive choice for such work. The emission of an 0·48-MeV. γ-ray in 11 per cent of the disintegrations[5] make it fairly easy to detect beryllium-7 by means of present-day γ-ray counters. Furthermore, detectable increases in beryllium-7 attributable to nuclear weapon tests have not been found as was the case for sulphur-35 (ref. 3).

The use of isotopic concentration as a means of measuring circulation and mixing stems from the inherently higher concentration prevailing in the stratosphere. The difference in concentration between stratosphere and troposphere is due primarily to the increase in cosmic-ray flux with altitude, and the resultant increase in isotope production via cosmic-ray neutrons as a function of altitude. In addition to lower initial production, the concentration within the troposphere is further reduced by the continual removal of activity by precipitation. Until recently all production-rates were based largely upon theory, but in 1960 Lal *et al.*[6] measured the rate of production of beryllium-7 directly in oxygen (water) exposed on Mount Evans, Colorado, and found the empirical results to be only 10 per cent higher than the calculated rate.

Beryllium-7 has been measured in surface air at Argonne National Laboratory (42° N., 88° W.) since mid-1959, at which time the concentration of γ-emitting fission products in air had diminished sufficiently so that the 0·48-MeV. line from beryllium-7 was readily apparent in the γ-ray spectrum of ashed air filters. The filters consisted of '*HV*-70' (Hollingsworth–Vose) filter paper mounted on 'Sutorbilt' air pumps and operated at flow-rates of 25–30 cubic metres per hr. The '*HV*-70' paper has an efficiency of 96 per cent for particles greater than $0{\cdot}25\mu$ in diameter. Filters from 8–10 air pumps operated continuously were grouped by calendar month and partially ashed at 300° C. (total ashing was not possible due to the presence of an asbestos base) prior to γ-counting. The volume of air from which particulates were removed was of the order of 10^5 cubic metres per month. The ashed residue was compacted into a cylindrical wafer and placed on a 5 × 4 in. sodium iodide (thallium) crystal for γ-ray spectrometric analysis. Both sample and detector (consisting of the crystal and a DuMont 6265 photomultiplier tube) were enclosed in a 9-in. thick steel shield with an inner shield consisting of 1 in. of mercury in a stainless steel annulus to achieve low background conditions. Pulse analysis was implemented using an Argonne type 256 channel analyser. Suitable sources of a number of fission products were used for standardization purposes. The concentrations of cæsium-137, zirconium-95, cerium-144, antimony-125, ruthenium-106, and beryllium-7 were determined by a method utilizing a combination of simultaneous equations and successive approximations.

The concentrations of beryllium-7 and cæsium-137 expressed in curies/cubic metre of air are shown in Fig. 1. The cæsium-137 measurements extend from January 1959 to the end of 1960, whereas those for beryllium-7 start in August 1959 and are corrected for decay to the middle of the month of collection. Both radionuclides exhibit maximum concentrations during the spring of 1960, and cæsium-137 shows a similar maximum in 1959. Such maxima, in the absence of recent nuclear tests, are attributed to the disruption of the northern hemisphere tropopause in middle latitudes during the spring months, resulting in an influx of high-altitude debris, much of it of polar origin, into the lower atmosphere. A repetition of the beryllium-7 maximum in 1959 is not seen owing to lack of data prior to August 1959; however, a similar trend in beryllium-7 concentration in surface air was noted by Cruikshank, Cowper and Grummitt[7] at two sites in Canada in 1954.

Following the period of maximum concentration, the level of cæsium-137 diminishes rapidly, proceeding at a rate in accord with that ascribed to removal of tropospheric debris by precipitation (~ 30 day half-

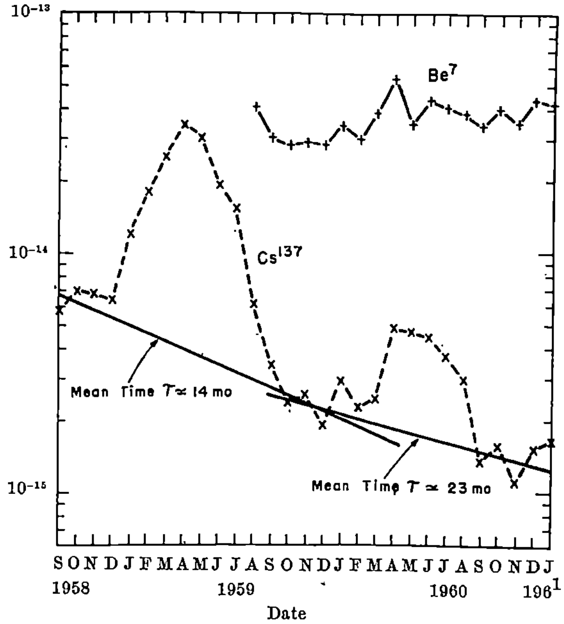

Fig. 1. Concentration of beryllium-7 and cæsium-137 in surface air at Argonne National Laboratory

time). The level of beryllium-7, on the other hand, decreased slightly and then remained at a substantially higher concentration than that observed prior to the maximum until the end of 1960. The difference in behaviour between beryllium-7 formed at a constant (though not homogeneous) rate throughout the entire atmosphere and cæsium-137 coming entirely from the stratosphere is an intriguing one, particularly in that it may provide information regarding transport of debris from the stratosphere into the troposphere. The apparent increase in beryllium-7 during the summer of 1960 might have been due to a decrease in precipitation, resulting in a lower rate of removal, and hence a build-up toward true equilibrium between production and radioactive decay. If precipitation is indeed the controlling factor, then the effect should have been in the opposite direction ; the beryllium-7 in surface air should have decreased since rainfall is more abundant during the summer months in middle and northern latitudes in the United States and Canada.

It appears that there was an actual increase in the concentration of beryllium-7 in the troposphere during the summer of 1960, and by inference during the summer each year. The basis for such a hypothesis is shown in Fig. 2, in which the reciprocal of the average monthly beryllium-7 concentration in surface air ($1/N$) is plotted as a function of the fraction of the annual precipitation which fell during the previous month (R), according to the method of Cruikshank *et al.*[7]. The assumption is made that equilibrium exists between beryllium-7 production and removal in the troposphere. Hence:

$$Q = \Lambda N \qquad (1)$$

where Q is rate of production of beryllium-7 in atoms/litre/day; Λ is rate of removal of beryllium-7 per day $= \lambda + kR$; λ is disintegration constant of beryllium-7 per day; R is fraction of annual precipitation falling in previous month; k is removal by precipitation per day; N is concentration of beryllium-7 in atoms/litre.

Equation (1) may also be written as:

$$1/N = \Lambda/Q = \lambda/Q + kR/Q \qquad (2)$$

Values of $1/N$ show a considerable range for a given value of R, the variation being outside the statistical accuracy of the determinations. For the most part the points appear to belong to two distinct groups as shown by the weighted average of each set. The intercept at $R = 0$ provides a measure of the production rate Q according to the relationship $1/N = \lambda/Q$. It should be noted that a higher concentration occurred during April–August 1960 and in August 1959. The variation in precipitation is similar during the periods of different production rate (that is, different concentration) and would seem to indicate that the difference is not due to this source. Although local precipitation values were used, they are qualitatively representative of those pertaining over a much wider area. The true effect of rainfall was probably seen during the autumn of 1960 when the beryllium-7 in surface air was consistently higher than in 1959 whereas the precipitation was markedly lower than in the autumn of 1959. The fact that the $1/N$ values fall in the low production group during this period lends support to this contention.

The question now arises as to the source of the increase in beryllium-7 concentration during the summer months. Prolonged increases in cosmic-ray intensity may be ruled out as none was observed. An increase would result if the release of beryllium-7 from the stratosphere were greater in summer than in winter. A related parameter, which varies seasonally, is the height of the tropopause in middle and northern latitudes, rising in summer and sinking to lower altitude in winter. As a result, regions of higher production of beryllium-7 will be included in the troposphere during summer and will be located within the stratosphere during the colder season. If this is the physical mechanism involved, it should be possible to verify it, in a crude way at least, by considering the change in production rate as a function of tropopause height. In the vicinity of 40° N. the mean winter tropopause is located at 33,000–35,000 ft. and that in summer at 45,000–48,000 ft. The

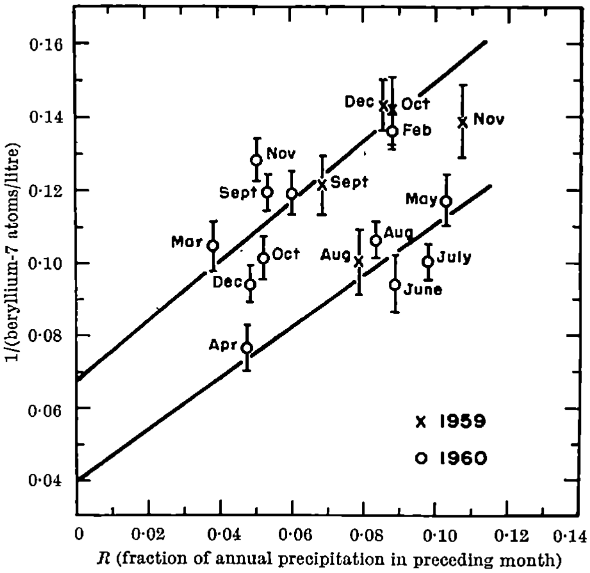

Fig. 2. Concentration of beryllium-7 in air as a function of precipitation

values of Q obtained from Fig. 2 are 0·37 and 0·20 atoms/litre/day or 260 and 130 atoms/cm.^{2}/day for high and low production respectively. These values are a full order of magnitude lower than the value of 2,200 atoms/cm.^{2}/day computed by Lal[2], including the empirical correction, for beryllium-7 production in the troposphere at 55° N. geomagnetic latitude. Because of inhomogeneities within the troposphere caused by incomplete mixing, removal of debris by precipitation preferentially from only the lower levels, as well as loss at the surface owing to dry deposition and impingement, measurements of air-borne debris made at ground-level are not representative of the mean level present throughout the troposphere. The existence of a fairly steep concentration gradient of air-borne debris between ground-level and the tropopause has been noted in aircraft profile studies[8]. Integration of the cæsium-137 and gross fission product concentration as a function of altitude during the spring and summer of 1960 indicated that an average factor of 13·5 existed between mean tropospheric concentration and that found at ground-level in the first half of 1960. The same factor was also found applicable to beryllium-7 concentration[9]. Converting the surface production values found from Fig. 2 into those for the mean troposphere yield values of 1,755 and 3,510 atoms/cm.^{2}/day for winter and summer production, respectively, which are in fair agreement with that of 2,200 atoms/cm.^{2}/day given by Lal[2]. The corresponding stratospheric production rate at this latitude computed by Lal is 9,400 atoms/cm.^{2}/day. The mass of air present between 35,000 and 50,000 ft. is 13 per cent of the total mass in a vertical column extending from the surface to 50,000 ft. The effective mean production within the summer troposphere using this mass distribution and Lal's values for tropospheric and stratospheric beryllium-7 production is found to be :

$$Q_s = 0{\cdot}87 \times 2{,}200 + 0{\cdot}13 \times 9{,}400 = 3{,}130 \text{ atoms/cm.}^2\text{/day}$$

There is reasonably good agreement between this figure and that of 3,510 atoms/cm.^{2}/day obtained from Fig. 2, particularly since no consideration has been given to transverse mixing of air which might further vary the apparent production of beryllium-7 as it is also a function of geomagnetic latitude.

If the concept can be accepted that the increase in concentration of beryllium-7 at the surface is due to the elevated tropopause, then it should be possible to relate the cæsium-137 concentration in the region of 35,000–50,000 ft. during and following the time of the maximum to that observed afterwards in surface air. The cæsium-137 present in the troposphere several months after a nuclear test may be considered to arise from continual leakage through the tropopause plus varying amounts of additional activity periodically injected by the spring break and the rising tropopause. The minima in levels of cæsium-137 in surface air seen in Fig. 1 during the autumn and winter are probably most closely a measure of the continual, 'steady state', removal of stratospheric debris by diffusion and minor fluctuations in the tropopause. Thus the amount of surface activity due to leakage during May–July 1960 should have been intermediate to the levels seen during late 1959 and the autumn of 1960. For May–July a concentration of 2×10^{15} curie/cubic metre was taken for cæsium-137 due to leakage (Fig. 1), which multiplied by 13·5 becomes $2{\cdot}7 \times 10^{-14}$ curie/m.^{3} for the mean concentration in the troposphere. Again using a value of 13 per cent for the fraction of the total air mass in the summer troposphere contained between 35,000 and 50,000 ft., and the observed value of $4{\cdot}5 \times 10^{-13}$ curie/m.^{3} for the cæsium-137 concentration in this region[10], a concentration of $\sim 6 \times 10^{-15}$ curie/m.^{3} is derived for the surface during May–July 1960. The measured concentration during this time varied from 3·8 to $4{\cdot}5 \times 10^{-15}$ curie/m.^{3}. The essential agreement between observed and calculated values tend to support the hypothesis that the rising tropopause causes the mass transfer of debris from the lower stratosphere into the troposphere from whence it is readily removed by means of precipitation and dry deposition.

The relative importance of the rising tropopause and the spring break as they affect the total removal of stratospheric debris may be estimated by integrating the total cæsium-137 found in surface air and that presumed to come only from steady-state removal. Taking a cycle extending between successive autumn minima, it was found that from the autumn of 1958 to the autumn of 1959, 75 per cent of the removal occurred via the spring break and the rising tropopause, whereas only 40 per cent was so removed during the autumn of 1959 to autumn 1960. Of these two mass transfer processes, that of the spring break is probably more important. The greater removal during the autumn of 1958 to the autumn of 1959 is presumably due to the fact that debris from the Soviet tests in October 1958 was essentially all removed by the end of 1959. Further evidence of the importance of these perturbations to steady-state removal may be seen by considering the mean stratospheric residence-time. Since the autumn minima are believed to reflect continual steady-state removal of stratospheric debris, the relationship between successive minima, as indicated in Fig. 1, should yield information relative to the mean stratospheric residence-time. During 1958–59 the mean time so derived was approximately one year, and during 1959–60 it lengthened to more than 20 months. Hence were it not for the seasonal increases in the rate of removal of nuclear debris from the stratosphere the mean residence-time would be approximately twice what it is. The non-uniformity in the rate of stratospheric removal adds to the complexity of fall-out mechanics; however, its proper consideration and better understanding will not only improve the accuracy with which ground contamination from present stratospheric debris may be predicated, but will also further our knowledge of the meteorology of the upper atmosphere.

This work was performed under the auspices of the U.S. Atomic Energy Commission.

We are indebted to Dr. J. Sedlet of the Industrial Hygiene and Safety Division of this Laboratory for the use of air filters from his collection network.

SUSTAINED OSCILLATIONS IN A CATALYTIC CHEMICAL SYSTEM

By R. A. SPANGLER* and F. M. SNELL

Department of Biophysics, University of Buffalo School of Medicine, Buffalo, New York

TO account for some features of periodic phenomena observed in biological organisms, the existence of some autonomous timing mechanism, or 'living clock', has been postulated. Although many different properties of these periodic phenomena have been reported, two characteristics are of particular theoretical interest. The frequency in certain instances is virtually independent of temperature, while in a variety of species the clock appears to be subject to external synchronization and modulation[1-3]. Any theoretical consideration of a timing mechanism must be reconciled with these observations[4].

Based entirely on chemical kinetic considerations, model mechanisms which exhibit periodic behaviour may be formulated. Because of the fundamentally dissipative nature of non-equilibrium chemical processes, however, certain non-linearities of reaction kinetics must be exploited to generate undamped oscillations in a system with a finite number of variables[5,6]. As early as 1920, Lotka[7] demonstrated a theoretical basis for undamped oscillations in a sequential series of autocatalytic reactions, a class of systems which has been treated in general by Moore[8]. More recently, Holmes[9] has discussed another non-linear kinetic mechanism, but has resorted to a discontinuous reaction coupling function to achieve oscillatory behaviour. The relationship to biological reality of both these system classes would appear remote.

Using a steady-state analytical approach as well as digital and analogue computer techniques, we have undertaken a study of the periodic behaviour exhibited by a particular realistic class of catalytic reaction systems. Being a type of relaxation oscillation, the periodicity of this system is non-harmonic in nature, and sustained oscillations may be achieved over a reasonably wide range of parameter values.

Consider a cross-coupled catalytic system formulated as follows:

$$\begin{gathered}\text{source. } A \rightarrow A + E \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} B \xrightarrow{k_2} E + P \xrightarrow{k_3} \text{sink } P \\ \alpha P + E' \underset{k_{-4}'}{\overset{k_4'}{\rightleftarrows}} I' \qquad \alpha P' + E \underset{k_{-4}}{\overset{k_4}{\rightleftarrows}} I \qquad (1) \\ \text{source } A' \rightarrow A' + E' \underset{k_{-1}'}{\overset{k_1'}{\rightleftarrows}} B' \xrightarrow{k_2'} E' + P' \xrightarrow{k_3'} \text{sink } P'\end{gathered}$$

The parameter α is the stoichiometric number for the association of the product (P or P') of one reaction sequence with the catalyst (E' or E) of the other to form an inactive complex (I' or I).

Under steady-state conditions, the following implicit relationship may be derived:

$$\left(\frac{k_3P}{k_2E_t - k_3P}\right)\left(1 + K_4\left[\frac{k_1'k_2'E_t'A'}{k_3'(k_2' + k_{-1}')(1 + k_4'P^\alpha) + k_1'k_3'A'}\right]^\alpha\right) - \frac{k_1A}{k_2 + k_{-1}} = 0$$

$$J_{ss} \equiv k_3P \qquad K_4 \equiv \frac{k_4}{k_{-4}} \qquad K_4' \equiv \frac{k_4'}{k_{-4}'} \qquad (2)$$

where the species symbols are used to denote concentrations. J_{ss} is the unprimed steady-state reaction flux, defined as k_3P; E_t and E_t' are the total catalyst concentrations which are conserved.

When $\alpha = 1$, the partial derivative $\left(\frac{\partial J_{ss}}{\partial A}\right)_{A'}$ remains positive and finite; thus J_{ss} is a single-valued function of A for all positive values of A. However, with $\alpha = 2$, the derivative may become negative over a limited range of A-values, passing through infinity at the boundaries of the region. J_{ss} becomes a multi-valued function of A in this region, and the form of the relationship under these conditions with A' constant appears in Fig. 1.

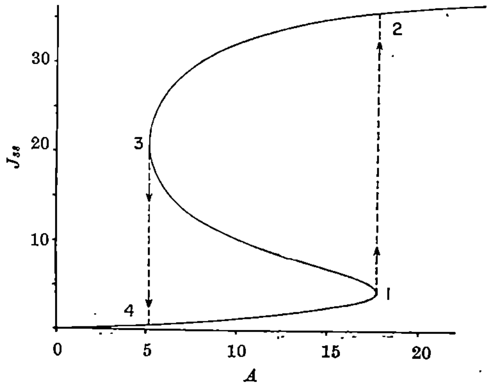

Fig. 1. Steady-state reaction flux J_{ss} plotted against reactant concentration A, as given by equation (2) with constant $A' = 10$. Axes are in arbitrary units of appropriate dimensions. Rate-constants employed for this solution are: $k_1 = k_{-1} = k_2 = k_4 = 1$; $k_3 = 0{\cdot}4$; and $k_{-4} = 0{\cdot}5$, with $k_i' = k_i . E_t = E_t' = 4$. Numbers on the curve are referred to in the text

It may be seen that this steady-state solution bears analogy to certain negative impedance devices, for example, the tunnel diode. Each possesses a region of negative slope, and each exhibits bi-stable, 'flip-flop' characteristics in this region. If, for example, A is varied cyclically over a range including the negative slope region, again with A' held constant, the system will proceed along the trajectory indicated by the dashed lines in Fig. 1, passing directly from point 1 to point 2 for increasing A, and from 3 to 4 as A is decreased. Thus the system exhibits what is analogous to a hysteresis loop in the phase-plot of steady-state conditions.

In the conditions that A is fixed at arbitrary concentrations, the negative slope portion of the continuous curve corresponds to possible stable steady-state solutions, although this segment is accessible only in rather physically unrealizable circumstances. On the other hand, if the influx of reactant A, J_A^{in}, is fixed, making A a dependent variable, this region of negative slope is characterized by instability; any random fluctuation from a given steady state in this region can only lead to

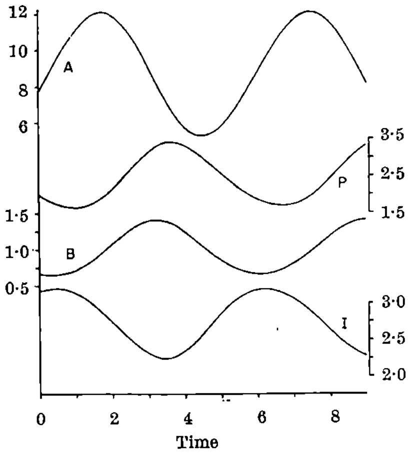

Fig. 2. Digital computer solution of the set of differential equations representing the system (1) with constant $J_A^{\text{in}} = J_{A'}^{\text{in}} = 1$. Chemical concentrations are plotted as a function of time with axes in arbitrary units. Rate-constants and the E_i's are the same as given in Fig. 1

greater deviation in the same direction. In these circumstances, then, with J_A^{in} between points 1 and 3 of Fig. 1, oscillations would in general be expected, since no stable steady-state solution exists which is compatible with the magnitude of flux from the source. Specifically, the system would be expected to trace in an anti-clockwise direction a closed trajectory in the phase-plot, roughly similar to the hysteresis loop, but not coinciding precisely because of departures from steady-state conditions. No general analytical solution for this dynamic situation exists, and it must be repeated that the foregoing analysis is based on the assumption of steady-state conditions and a constant A' concentration. The oscillations predicted by this analysis are evident, however, in the digital and analogue computer solutions of the dynamic system. Furthermore, oscillatory behaviour has been observed in the computer solutions of the fully symmetrical system in which both J_A^{in} and $J_{A'}^{\text{in}}$ are fixed. An example of these oscillations may be seen in Fig. 2.

Further work is in progress on this and other classes of reactions in an effort to delineate the detailed conditions for sustained oscillation. Preliminary observations, however, suggest several general properties of this particular system. It would appear, for example, that the frequency of oscillation of the complete system is less dependent, thermally, than the individual reactions, and it is conceivable that complete temperature compensation may be obtained by having appropriate relationships among temperature coefficients of the rate constants. It also appears that the period of oscillation is one-to-several orders of magnitude larger than the time-constants of the individual uncoupled catalytic reactions, a feature possibly of significance in consideration of the long periods of some biological phenomena. In addition, several means by which external stimuli may modulate the phase or frequency of oscillation suggest themselves, such as by alteration of either the reactant influx or the total catalyst concentration.

In view of these preliminary results and the feasibility of the assumptions involved, it appears that biological periodicity may be based entirely on chemical kinetic systems, without resort to diffusive or phase boundary effects. The model discussed here is proposed as one specific mechanism possibly underlying the biological clock.

MINIMUM ENERGY THEOREM FOR FLOW OF DRY GRANULES THROUGH APERTURES

By R. L. BROWN

British Coal Utilization Research Association, Leatherhead, Surrey

ALTHOUGH the motion of granules flowing down a vessel to escape through an aperture is complex, the flow-rate (Q gm./sec.) over small intervals of time is remarkably steady. It seems permissible to represent the average flow by stream-tubes in a continuum of density ρ gm./c.c. Then conservation of number flowing in a stream-tube gives:

$$N_1 \mathrm{d}A_1 = N_2 \mathrm{d}A_2 \tag{1}$$

where N granules per cm.²/sec. are flowing orthogonally to an elementary area $\mathrm{d}A$ (Fig. 1). If v cm./sec. is the velocity of the continuum normal to $\mathrm{d}A$:

$$\rho v = mN \tag{2}$$

where m gm. is the weight of a granule. It is assumed that the granules all have the same weight.

Consider an elementary volume $\mathrm{d}\tau$ c.c. at co-ordinates (R,θ). The mass is $\rho \mathrm{d}\tau$ gm., the height above the origin of co-ordinates is $R \cos\theta$ cm. and the velocity v cm./sec. Writing $T\mathrm{d}\tau$ for the sum of the potential and kinetic energies:

$$2T = \rho(v^2 + 2gR\cos\theta) \tag{3}$$

Now it is well known[1] that the flow-rate Q does not vary with the head of material in the vessel, except perhaps at very small heads. Pressure is not transmitted far in a granular mass, owing to the development of arches and to frictional forces between granules. These considerations suggest that the pressures on the faces $\mathrm{d}A$ of the volume $\mathrm{d}\tau$ do little or no work. Energy is dissipated, however, on the

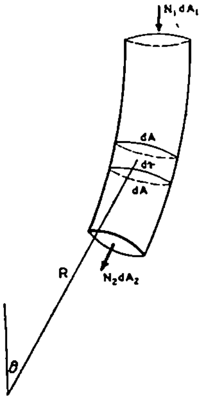

Fig. 1. Stream-tube in continuum

curved surface of dτ and by collisions, rotations and frictional forces within dτ. It is postulated therefore that the energy T per unit volume decreases in the direction of flow along a stream-tube. Remembering that the granules below the aperture are falling freely (apart from collisions in horizontal planes), the vertical pressure just above the aperture cannot be large, and it seems likely that the energy postulate will hold at least in the neighbourhood of the aperture, provided that there is no appreciable cohesion between granules.

Above apertures in a horizontal base plate, a portion of the mass resting on the base is stationary, and the stream-tubes are forced to converge. Visual observation suggests that, to the first order, the flow takes place in a straight-sided wedge or cone with half-angle β (Fig. 2). The simplest way of satisfying the continuity equation (1) is to take the stream-tubes to be radial. Then for plane flow between parallel vertical plates, distant l cm. apart, through a slit of width S cm.:

$$N = \frac{AK(\theta)}{R} \tag{4}$$

whence, taking A independent of (R,θ),

$$Q = 2mAl\int_0^\beta K(\theta)\mathrm{d}\theta \tag{5}$$

For axial flow down a cylinder through a circular aperture of diameter D cm.:

$$N = \frac{BL(\theta)}{R^2} \tag{6}$$

and

$$Q = 2\pi mB\int_0^\beta L(\theta)\sin\theta\mathrm{d}\theta \tag{7}$$

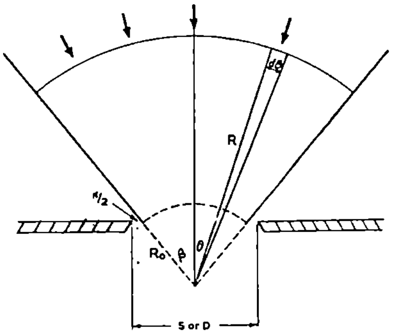

Fig. 2. Flow in a wedge or cone

It has been shown elsewhere[2] that there is an effectively empty annulus, of width $k/2$ cm., adjacent to the edge of the aperture. k is the same for slits and circles and depends *inter alia* on the size of the granules. This annulus can be taken into account (Fig. 2) by locating the vertex of the wedge or cone a distance R_0 cm. from the edge of the annulus, where:

$$2R_0\sin\beta = (S-k) \text{ or } (D-k) \tag{8}$$

In what follows it will be assumed that ρ is constant throughout the wedge or cone, apart from a possible discontinuity at $\theta = \beta$. Thus v is taken to be proportional to N.

Then in plane flow, equations (2), (3) and (4) give:

$$2T = \rho\left[\frac{m^2A^2K^2(\theta)}{\rho^2R^2} + 2gR\cos\theta\right] \tag{9}$$

which has a minimum at R_m where:

$$gR_m^3 = \frac{m^2A^2K^2(\theta)}{\rho^2\cos\theta} \tag{10}$$

Likewise for cylindrical flow, equations (2), (3) and (6) give:

$$gR_m^5 = \frac{2m^2B^2L^2(\theta)}{\rho^2\cos\theta} \tag{11}$$

If the energy postulate that T decreases along a stream-tube is to hold, then the surface of minimum energy (R_m,θ) must lie below the wedge or cone.

The flow-rate Q may be expressed in terms of aperture size and the surface of minimum energy by means of equations (5), (7), (8), (10) and (11), namely:

$$\sigma = \frac{Q}{\rho l(S-k)\{g(S-k)\}^{1/2}} = \frac{\int_0^\beta (R_m/R_0)^{3/2}\cos^{1/2}\theta\mathrm{d}\theta}{2^{1/2}\sin^{3/2}\beta} \tag{12}$$

$$\gamma = \frac{4Q}{\rho\pi(D-k)^2\{g(D-k)\}^{1/2}} = \frac{\int_0^\beta (R_m/R_0)^{5/2}\cos^{1/2}\theta\sin\theta\mathrm{d}\theta}{\sin^{5/2}\beta} \tag{13}$$

It would not be unexpected in flow from wide vessels to have β a constant, determined by material characteristics. If this were the case, equations (12) and (13) show that σ, γ are constants, provided (R_m/R_0) is a function of θ, β only. Experimental evidence has been given elsewhere showing that σ, γ are constants for several materials discharging from wide vessels through a range of aperture sizes[2]. Such discrepancies as have been noted, are small. (This is not the case for narrow vessels.) It would appear, therefore, that (R_m/R_0) is, to the first order, a function of θ, β only.

Now the sides of the wedge or cone at $\theta = \beta$ cease for $R \leqslant R_0$. Thus the surface $R = R_0$ can be regarded as an upper limit to the surface (R_m, θ) whence equations (12) and (13) yield upper limits for σ, γ:

$$\sigma_u = \frac{\int_0^\beta \cos^{1/2}\theta\mathrm{d}\theta}{2^{1/2}\sin^{3/2}\beta} \tag{14}$$

$$\gamma_u = \frac{2(1-\cos^{3/2}\beta)}{3\sin^{5/2}\beta} \tag{15}$$

It is interesting to note that, taking the average velocity around the arc of the wedge as $(Q/2R\beta l\rho)$ and

Table 1. FLOW FROM FLAT-BOTTOMED VESSELS

† A minimum value measured by fluidizing bed and then slowly reducing air flow to zero; used for ρ in equations 12 and 13.

the average height of the arc as ($R \sin \beta/\beta$), application of the minimum energy theorem at $R_m = R_0$ gives:

$$\sigma_{\text{av.}} = \frac{\beta^{1/2}}{2^{1/2} \sin \beta} \tag{16}$$

the corresponding equation for cylindrical flow being:

$$\gamma_{\text{av.}} = \frac{(1 - \cos \beta)^{1/2}}{2^{1/2} \sin^{3/2} \beta} \tag{17}$$

For values of β ranging to more than 70°, equations (16) and (17) differ by less than 1 per cent from equations (14) and (15), respectively. It would seem, therefore, that the flow-rates may not be very sensitive to the profiles $K(\theta)$, $L(\theta)$. These profiles are associated with the minimum surface (R_m, θ) by equations (10) and (11).

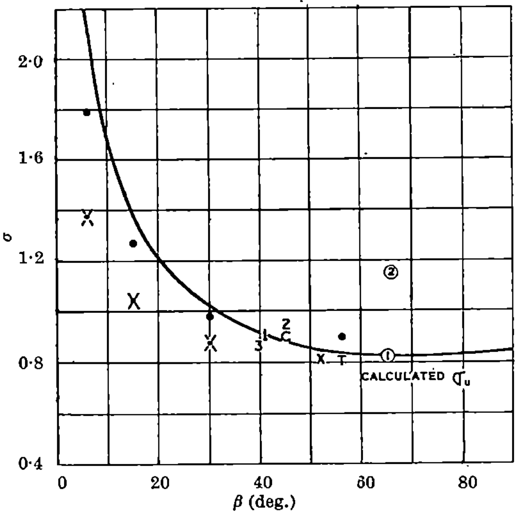

Fig. 3. Plane flow. Symbols are defined in Tables 1 and 2

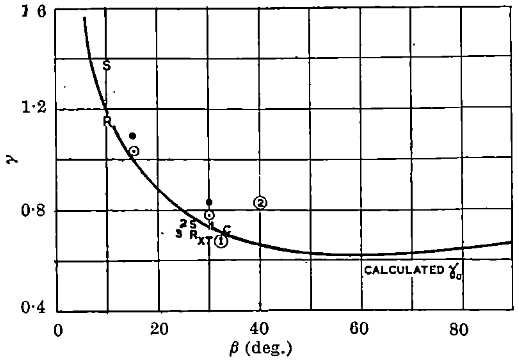

Fig. 4. Cylindrical flow. Symbols are defined in Tables 1 and 2

Data already published on σ,γ can be used to test whether the predicted relation of σ_u,γ_u with β, is valid. This is attempted first for flow from flat-bottomed vessels where the material forms its own wedge or cone. The angle β in plane flow was measured by observation through a 'Perspex' side plate. Marker particles were used in cylindrical flow; those emerging in the first runnings were noted. The estimates of β found by these methods are considered to be reasonably good; details will be given elsewhere. It was found that β for cylindrical flow was appreciably less than for plane flow (Table 1).

The observed values of σ,γ are plotted against β in Figs. 3 and 4. Agreement with the calculated values of σ_u,γ_u is seen to be good and it follows that the angle β of the wedge or cone is a major factor in determining the rate of efflux. It is satisfactory to see that in plane flow the experimental data follow the theoretical curve round to its minimum at about 65°. At larger values of β, flow would be taking place at angles below the angle of rest to the horizontal, which is clearly impossible. The theoretical equation for cylindrical flow exhibits a similar minimum flow-rate, but in practice the cone angle formed by the material is appreciably smaller than 60°.

Discrepancies appear in Figs. 3 and 4 for small glass beads, which are extremely mobile: this might be due to the effective wedge or cone angle being appreciably smaller than those reported in Table 1.

Also shown in Fig. 3 are data (Table 2) for flow of a rounded sand through troughs with half-angles of 30°, 15°, 6°, these being less than the natural wedge-angle of 56°. Two regimes of flow were found with the troughs, separated by a distinct discontinuity. At the higher slit-sizes Q was proportional to $(S - k)^{3/2}$

† As reported, a normal, not a minimum bulk density.

with the same k as for a flat-bottomed vessel; these points (●) follow the theoretical curve.

At the smaller slit-sizes Q still varied with $(S-k)^{3/2}$ but now k varied with trough angle and the flow-rates (×) were lower. Possibly, the 'crowdedness' of the emerging granules is greater.

Results for cylindrical flow through conical hoppers are given in Fig. 4, by recalculating data reported by other workers (Table 2). Agreement with the theory is satisfactory.

The minimum energy theory applied to radial flow from wide vessels shows that σ or γ are determined respectively by the angle of the wedge or cone formed by the material itself, or for flow through a trough or conical hopper, by the angle of the trough or hopper. For flat-bottomed vessels the difference in β for plane and for cylindrical flow is an important fact for elucidation of the observed flow-rates.

Acknowledgment is made to the British Coal Utilization Research Association for permission to publish and to Mr. J. C. Richards and Mrs. J. Tee for assistance with the experiments.

COMPARATIVE ANALYSIS OF INACTIVATING EFFICIENCY OF RADIATION ON DIFFERENT ORGANISMS

By DR. M. TERZI

Istituto di Genetica, Università, Pavia

IN 1953, Epstein[1], and after him other authors, put forward an interpretation of the lethal effect (direct effect) of ionizing radiations based on the idea that the effect itself is exerted upon the nucleic acids. The dose – effect relationship was expressed as the ratio of volume of nucleic acids (calculated by other physical measurements) to 'target' volume. Their theory, however, suffered some limitations, since it gave an unsatisfactory fit when organisms other than small viruses were studied.

This interpretation can now be revised in the light of new structural data on nucleic acids, and extended to more complex organisms.

Available data are summarized in Table 1, which shows the following:

(*a*) The X-ray dose, expressed in roentgens, corresponding to $\exp^{-1}$ individuals surviving (D_0); such a dose is calculated from the logarithmic portion of the survival curve to radiations when the organisms were in a protecting medium or in a dry state. Survival is defined on the basis of infecting ability for viruses, or colony-forming ability for other organisms.

(*b*) The nucleic acid content of several organisms: for ribonucleic acid (RNA) viruses, it gives the RNA content; for all other organisms, the amount of deoxyribonucleic acid (DNA) is given: both are expressed in molecular weight units. Data were selected by choosing the most recent observations available in the literature. I have given two values when two limits are given by the same author, and also when two divergent results were published almost simultaneously. In order to reduce the number of references, I have often referred to reviews rather than to original papers.

(*c*) The lethal efficiency (e) per ion pair produced in the nucleic acids corresponding to the dose D_0.

(*d*) The mean energy (in ergs) absorbed by nucleic acids; this value is termed E and it is inversely proportional to the efficiency of inactivation.

The values for e and E are plotted in Fig. 1 in a randomized order; this procedure (suggested to me by Prof. M. Ageno) enables a non-biased evaluation of the groupings.

One can see that four different levels, expressing inactivation efficiency, correspond to four systematically distinct groups. The different degree of complexity of their genetic structure justifies their reaction to ionizing radiations.

The first level ($\bar{e} = 0{\cdot}64$) corresponds to single-stranded DNA or RNA viruses; such data are in good agreement with those obtained by Hutchinson[2] ($\bar{e} = 0{\cdot}51$) with some forty dried proteins irradiated with electrons, and with the results of Aurisicchio *et al.*[3] on the efficiency of assimilated phosphorus-32 decay of alpha phage.

At the second level one finds animal and bacterial viruses containing double-stranded DNA. In this group $\bar{e} = 0{\cdot}62 \times 10^{-1}$ in agreement with the figure calculated by Hershey *et al.*[4] for the assimilated phosphorus-32 decay of the T-even phages. The vaccinia virus (No. 2) shows an aberrant e value; some of its properties, however, such as its enzyme content[5] and the presence of many 'targets'[6], point independently to an unusual structure. It is not clear, on the other hand, why *Haemophilus influenzae* should belong to this group.

It is worth pointing out that the differences in E values between the first and second group cannot depend on the particle size, because both groups are extremely variable in this respect.

In the third group ($\bar{e} = 1{\cdot}23 \times 10^{-2}$), bacteria and haploid yeast are represented. The finding (Morse *et al.*[7]) that crossing-over in *E. coli* occurs at the four-strand stage indicates that the hereditary structure

* For references, see footnotes Table 1.

of bacteria is closer to that of yeast (a conventional halpoid organism) than to that of bacteriophages.

It may be mentioned that isolated DNA or RNA of different organisms (tobacco mosaic virus, *Haemophilis influenzae*, *Diplococcus pneumoniae*) show the same e value as the organism from which they are derived (see Table 2). In the case of *Diplococcus pneumoniae*, the transforming principle shows a two-slope survival curve. The value of E calculated from the slowly inactivated part shows no significant departure from E for the whole cell, while the E calculated from the fast inactivated portion of the curve is close to the E of the second group. But it is not known whether the molecular weights of the two fractions—if there are actually two fractions—are equal or not. No conclusion can therefore be reached here.

Cells from vertebrates, including man, and from yeast with ploidy greater than 1, can be placed together in the fourth group ($\bar{e} = 0·69 \times 10^{-3}$).

The fact that the inactivating efficiency for organisms of ploidy greater than 1 is lower than that for haploid cells is shown qualitatively by the different slopes of the exponential portion of the survival curves of haploid and diploid yeast cells[8]. The different efficiencies have been interpreted as due to different killing mechanisms. In haploid cells, recessive lethals (probably point mutations and/or small deficiencies) account for a rather high proportion of total lethality, whereas in polyploid organisms the most efficient type of lethals is the dominant factor (probably chromosomal aberrations or breakages).

It is difficult to offer a physical interpretation of these results. From a biological point of view, it can be said that there are discrete levels of structural organization corresponding to well-defined degrees of radiosensitivity, which seems to decrease with increasing structural complexity from single-stranded DNA to the chromosome of haploid organisms. The further decrease of radiosensitivity from haploid to di- and poly-ploid could be due, however, to a change in the phenogenetic pattern of lethality rather than to increased complexity.

It would be very useful to collect new data and compare them with other parameters related to radiosensitivity. I was limited to the use of those unicellular organisms and those cells behaving like colony-forming organisms, because colony formation appears to be a uniform and reliable way of comparing the efficiency of ionizing radiation. From a physical point of view, it can be suggested that the inactivation of more complicated structures needs perhaps larger ionization clusters, which are obviously rarer. It would also be interesting to compare the above data with others on the mutation frequency in cistrons of known length, to see if gene mutation can also show different degrees of radiosensitivity in organisms of different complexity.

I am indebted to Prof. F. Graziosi, of the University of Rome, for very valuable discussion during the preparation of this communication. The work was supported by a grant from C.N.E.N., Rome.

FORMATION AND UTILIZATION OF POLY-β-HYDROXYBUTYRIC ACID BY KNALLGAS BACTERIA (*HYDROGENOMONAS*)

By Prof. H. G. SCHLEGEL, G. GOTTSCHALK and R. VON BARTHA

Institut für Mikrobiologie der Universität, Göttingen

THE conclusion that hydrogen-oxidizing bacteria of the *Hydrogenomonas* type are rich in storage material and are able to synthesize it from carbon dioxide and molecular hydrogen has been drawn from three types of experiments: (*a*) the intensity of endogenous respiration remains nearly constant for relatively long periods of aerobic incubation; (*b*) when chemolithotrophically growing cells have reached the stationary growth phase, turbidity continues to increase while the total cell count remains constant; (*c*) washed cells suspended in phosphate buffer oxidize hydrogen in the presence of carbon dioxide three times as fast as they do in its absence. In these conditions, carbon dioxide is assimilated in substrate amounts and incorporated into a cell fraction which amounted to 65 per cent of the dry weight of cells. The solubility in chloroform, the insolubility in ethyl–ether and petroleum ether, and the resistance to potassium hypochlorite solution indicated that the storage material was poly-β-hydroxybutyric acid. This polymeric material is accumulated in the cells when, in the absence of nitrogen or phosphorus, protein synthesis and growth are inhibited, or when the cells have reached the stationary phase of growth.

For identification of the storage material three strains of *Hydrogenomonas* (*H*1, *H*16 and *H*20) were used which had been enriched under chemolithotrophic conditions and isolated independently from each other. The strains differed from one another in several physiological characteristics. They were grown in submerged culture[1]. At the end of the exponential growth phase, the cells were collected, washed and suspended in phosphate buffer. The suspension was stirred (650 r.p.m.) in an atmosphere of hydrogen (60 per cent), oxygen (30 per cent), and carbon dioxide (10 per cent) at 28° C. for 30 hr. In other experiments the nitrogen source in the growth medium was restricted to 300 mgm. ammonium chloride/litre. After having reached a density of 0·75 mgm. dry weight/ml., the cells stopped growing; further increases in dry weight and turbidity were caused by the synthesis of poly-β-hydroxybutyric acid (Table 1).

Table 1. INCREASES IN DRY WEIGHT AND IN POLY-β-HYDROXYBUTYRIC ACID CONTENT IN *Hydrogenomonas H*20 DURING CHEMOLITHOTROPHIC GROWTH FOLLOWING DEPLETION OF THE NITROGEN SOURCE

Incubation time (hr.)	Cell dry weight (mgm./ml.)	Poly-β-hydroxybutyric acid (mgm./ml.)
42	0·75	0·234
111	1·55	1·012
Increase	0·80	0·778

Cells were grown in a mineral medium containing 300 mgm. ammonium chloride/litre in an atmosphere of 60 per cent hydrogen + 30 per cent oxygen + 10 per cent carbon dioxide, *p*H 7·0, 28° C. Cell protein increased up to the thirty-ninth hour and then remained constant.

The accumulation of poly-β-hydroxybutyric acid during the fixation of carbon dioxide in the absence of a source of nitrogen can be demonstrated in a series of micrographs of thin sections (Fig. 1, *a*–*c*.) In log-phase cells no structures other than nuclear material can be detected. After a 12-hr. period of carbon dioxide fixation, several round and oval areas become visible which show a distinct boundary and appear empty. These areas undoubtedly are inclusions of poly-β-hydroxybutyric acid. After a 48-hr. period of carbon dioxide fixation, the whole cell is filled with a few large inclusions of poly-β-hydroxybutyric acid which displace the chromatin bodies and the cytoplasm into a minimum possible area at the periphery and the interstitial areas between the inclusions. Since the density of these areas is even less than the

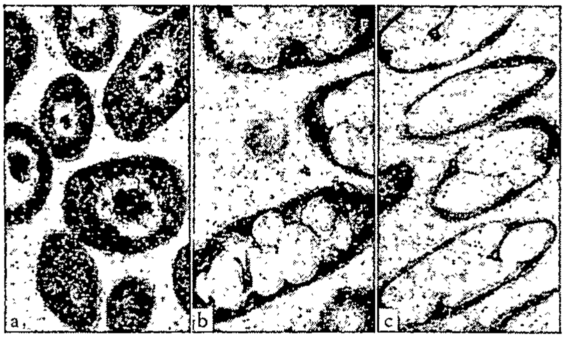

Fig. 1. Electron-micrographs of thin sections of *Hydrogenomonas* *H*16 showing the formation of inclusions of poly-β-hydroxybutyric acid during incubation in phosphate buffer under an atmosphere o 70 per cent hydrogen + 20 per cent oxygen + 10 per cent carbon dioxide for 0 hr. (*a*, log-phase cells), 12 hr. (*b*) and 48 hr. (*c*) Fixation for 2 hr. at 3° C. with 0·5 per cent osmic acid at *p*H 8·0 (veronal acetate buffer); embedded in methacrylate. Electron-microscopical preparations and studies were carried out by Mr. K. Kran. (× 21,500)

density of the surrounding methacrylate of the section, it is concluded that the poly-β-hydroxybutyric acid dilutes the embedding medium.

In order to isolate the storage material, the washed cells were treated with potassium hypochlorite solution (Williamson and Wilkinson's method[2]). The residue, washed with water, ethanol and ethyl-ether, was almost completely dissolved in hot chloroform and after filtration could be re-precipitated with ether. Using this method at a temperature of 0° C., 0·4 vol. of ether will precipitate 7·4 per cent of the storage material, while 0·52 vol. precipitates 33·0 per cent and 1·2 vol. 100 per cent. The melting points and analytical determinations of the purified storage materials derived from *H*1, *H*16 and *H*20 are shown in Table 2. Furthermore, poly-β-hydroxybutyric acid preparations were analysed which had been isolated from *Bacillus megaterium* and *Azotobacter chroococcum*, in both of which poly-β-hydroxybutyric acid had previously been found[3,4]. The different melting-point intervals of the preparations indicated different degrees of polymerization.

Table 2. MELTING POINTS AND ANALYTICAL RESULTS FOR POLY-β-HYDROXYBUTYRIC ACIDS ISOLATED FROM DIFFERENT BACTERIA

Organism	Melting point	C (per cent)*	H (per cent)*
Azotobacter chroococcum	150–155	55·4	7·0
Bacillus megaterium	168–173	55·6	6·9
*Hydrogenomonas H*1	162–166	55·6	7·1
,, *H*16	158–162	55·4	7·0
,, *H*20	167–172	55·6	7·4

* The theoretical values calculated for $(C_4H_6O_2)_n$ are: C = 55·8 per cent; H = 7·0 per cent.

The infra-red spectra of all five substances examined by us were identical. Dry distillation of poly-β-hydroxybutyric acid gave crotonic acid with a yield of 70 per cent. After recrystallization from water, this crotonic acid melted at 70° C. Crotonic acid amide prepared from this acid had a melting point of 160° C. These two derivatives, prepared from extracted poly-β-hydroxybutyric acid, were found to be identical with pure crotonic acid and the crotonic acid amide prepared from it. No depression of the melting points was observed on mixing the substances obtained from extracted poly-β-hydroxybutyric acid with the chemically pure compounds. Free β-hydroxybutyric acid could be prepared by means of alkaline hydrolysis of poly-β-hydroxybutyric acid and ether extraction of the acidified hydrolysate; this was verified by determination of the optical activity and using paper chromatography and reference substances.

In addition to the method for the preparation of poly-β-hydroxybutyric acid described by Williamson and Wilkinson[2], we have had good results with chloroform extraction of lyophilized cells. A rather pure product is prepared with quantitative yield when the dry powder is extracted with chloroform at room temperature, and the poly-β-hydroxybutyric acid precipitated with ether. Methylene chloride is as efficient as chloroform in extracting it.

The efficiency with which poly-β-hydroxybutyric acid is synthesized from carbon dioxide by oxidation of hydrogen was determined by a manometric method in a Warburg apparatus using $NaH^{14}CO_3$. The stoichiometric relationship of the gas mixture consumed to the carbon dioxide taken up was found to be 8–8·5 under the conditions of synthesis of storage material. It does not vary significantly from the corresponding relationship under growth conditions and agrees with the equation:

$$25H_2 + 8O_2 + 4CO_2 \rightarrow (C_4H_6O_2) + 22H_2O$$

During organotrophic metabolism poly-β-hydroxybutyric acid is also stored by *Hydrogenomonas* in considerable quantities (Fig. 2). With β-hydroxybutyric acid or crotonic acid serving as substrate, the speed with which the storage material is synthesized is even greater than in autotrophic conditions. When the cells are incubated with these substrates, it makes practically no difference whether they are in contact with air or with a hydrogen–oxygen mixture. Since

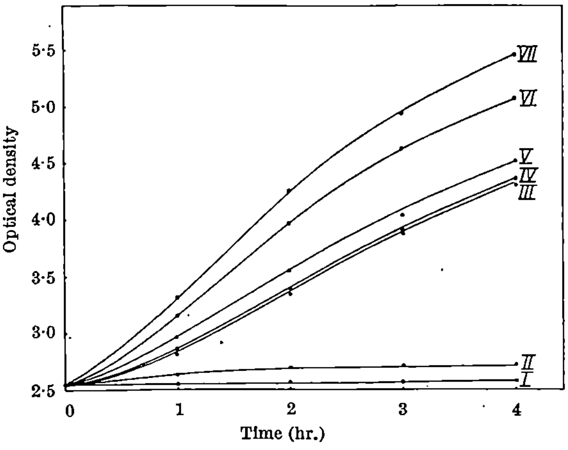

Fig. 2. Synthesis of poly-β-hydrobutyric acid by *Hydrogenomonas* *H*16 in nitrogen-free mineral medium with different sources of energy and carbon

		Increase in poly-β-hydroxybutyric acid (in mgm./mgm. cell protein) in the course of 4 hr. incubation
I.	Under air without carbon source	0·00
II.	Under nitrogen with β-hydroxybutyric acid	—
III.	Under air with crotonic acid	0·41
IV.	Under hydrogen + oxygen with crotonic acid	0·42
V.	Under hydrogen + oxygen + carbon dioxide	0·47
VI.	Under hydrogen + oxygen with β-hydroxybutyric acid	0·54
VII.	Under air with β-hydroxybutyric acid	0·66

20 ml. suspension (1 mgm. cell protein/ml.) in 200 ml. Erlenmeyer flasks were shaken at 30° C. under the conditions indicated (with 1 m*M* β-hydroxybutyric acid or crotonic acid per flask); measurement of turbidity at 436 mμ; determination of poly-β-hydroxybutyric acid gravimetrically after lyophilization of 10 ml. suspension, chloroform extraction and following precipitation with ether

only small amounts of energy seem to be necessary for the polymerization of the monomers taken up by the cell, these may easily be produced by substrate oxidation, with the result that the efficiency of the synthesis cannot be increased by simultaneous hydrogen oxidation. Other organic substrates have not yet been examined.

Cells containing little storage material (less than 10 per cent poly-β-hydroxybutyric acid) and those containing a great deal (more than 50 per cent) differ considerably in their endogenous respiration (Table 3). The former were collected prior to the end of the exponential growth phase, the latter 20 hr. after depletion of the nitrogen source. Oxygen uptake was determined manometrically with cell suspensions in phosphate buffer with and without addition of a nitrogen source (ammonium chloride).

Table 3. ENDOGENOUS RESPIRATION OF CELLS CONTAINING SMALL AND LARGE AMOUNTS OF POLY-β-HYDROXYBUTYRIC ACID
(μl. oxygen/mgm. protein/hr.)

Elapsed time (hr.)	PHBA-poor cells		PHBA-rich cells	
	$-NH_4Cl$	$+NH_4Cl$	$-NH_4Cl$	$+NH_4Cl$
2	12·4	16·0	22·7	37·2
5	4·5	4·7	16·2	30·8
8	3·0	3·2	14·6	25·9

Warburg vessels with 2·5 ml. suspension of *Hydrogenomonas H*20 in 0·06 *M* phosphate buffer at *p*H 7·0; 113·2 *μM* ammonium chloride/vessel; 0·2 ml. 20 per cent potassium hydroxide in central well; atmosphere, air; 30° C.

The endogenous respiration of rich cells is not only greater than that of cells containing little poly-β-hydroxybutyric acid, but is also greatly increased by the introduction of a nitrogen source. This boost in uptake of oxygen over and above endogenous respiration, which is brought about by the ammonium ion and which is not observed with cells poor in poly-β-hydroxybutyric acid, seems to indicate that the accumulated poly-β-hydroxybutyric acid is re-circulated into the metabolism and used for protein synthesis.

This hypothesis was verified by experiments in which the increase and decrease of poly-β-hydroxybutyric acid and cellular nitrogen were measured during endogenous respiration and during hydrogen oxidation, without carbon dioxide, of cells rich in poly-β-hydroxybutyric acid with and without a nitrogen source (Table 4).

Table 4. RE-UTILIZATION OF POLY-β-HYDROXYBUTYRIC ACID FOR PROTEIN SYNTHESIS BY *Hydrogenomonas H*16

Experimental conditions		Cell content		Difference after 12 hr.	
N-source	Atmosphere	Total N (mgm.)	PHBA (mgm.)	Total N (mgm.)	PHBA (mgm.)
Initial suspension		0·358	2·50	—	—
None	Air	0·369	2·30	+0·011	−0·2
Ammon. chloride	Air	0·546	0·67	+0·188	−1·83
None	70 per cent H_2 + 30 per cent O_2	0·367	2·47	+0·009	−0·03
Ammon. chloride	70 per cent H_2 + 30 per cent O_2	0·622	0·61	+0·264	−1·89

Suspension of chemolithotrophically grown cells (50 per cent poly-β-hydroxybutyric acid) in 0·067 *M* phosphate buffer at *p*H 7·0; 75 *μM* ammonium chloride/ml.; 28° C.; atmosphere, air or carbon dioxide-free hydrogen–oxygen mixture (70 per cent hydrogen + 30 per cent oxygen; carbon dioxide absorbed by 20 per cent potassium hydroxide); incubation time 12 hr. (with stirring); Kjeldahl method used to determine cellular nitrogen; poly-β-hydroxybutyric acid determined gravimetrically from lyophilized material after extraction with chloroform and precipitation with ether.

Under air, only a small percentage of the poly-β-hydroxybutyric acid is consumed by endogenous respiration. In the presence of ammonium chloride, the cellular nitrogen increases considerably at the expense of poly-β-hydroxybutyric acid. In an atmosphere of carbon dioxide-free hydrogen–oxygen mixture these effects are even more pronounced: while the poly-β-hydroxybutyric acid decreases, the cellular nitrogen accumulates to a considerable extent. Therefore we must assume that we are dealing with poly-β-hydroxybutyric acid as a genuine storage material, which in the absence of a carbon source can support metabolism, and can be used for protein synthesis in the presence of a nitrogen source. The efficiency of this synthesis is greater during hydrogen oxidation than during endogenous respiration.

The three strains of *Hydrogenomonas* examined up to the present time synthesize poly-β-hydroxybutyric acid chemolithotrophically as well as organotrophically and are able to re-utilize the storage material in their metabolism.

APPARENT CYTOPLASMIC INHERITANCE OF TYROSINASE COMPETENCE IN *STREPTOMYCES SCABIES*

By PROF. K. F. GREGORY and WEI-JEN SHYU
Department of Microbiology, Ontario Agricultural College, Guelph

STREPTOMYCES scabies, an etiological agent of potato scab, like other members of its genus, resembles the true bacteria in size and many physiological characteristics, but has a mycelial growth habit. The formation of nutritionally balanced heterokaryotic growth between pairs of nutritionally deficient strains has been demonstrated in several species of *Streptomyces*[1–3]. Infrequent genetic recombination, presumably preceded by nuclear fusion, occurs in some of these species, but the great majority of the spores formed by the heterokaryons have the nutritional requirements of one or the other of the two parental strains. Since the two parental-type nuclei share the same cytoplasm within the heterokaryon, any cytoplasmically inherited characteristic should be shared by uni-nucleate spores bearing both types of nuclei. This phenomenon appears to occur with the determinant for tyrosinase production in *Streptomyces scabies*.

Strains of *S. scabies* isolated from potato scab lesions are normally capable of forming a dark brown pigment (presumably melanin) in tyrosine-containing medium in contact with air. Tyrosinase-deficient mutants arise at a relatively high frequency, however, comprising about 0·2 per cent of the total colonies derived from non-irradiated spores and up to 5 per cent of the colonies developing from X-ray treated spores[4]. The tyrosinase-deficient state, by contrast, was found to be highly stable, and no back mutation to tyrosinase competence has been detected, following numerous platings of tyrosinase-deficient mutants during a 5-year period.

Strains of *S. scabies* have been observed cytologically to undergo frequent hyphal fusions[5]. Colonies, concluded to be nutritionally balanced heterokaryons, formed readily on minimal medium, when some pairs of mutants, each bearing two complementary nutritional deficiencies, were plated together. The great majority of the spores derived from these heterokaryons had the nutritional requirements of one or the other of the two parents, but usually in unequal proportions. Thus, in a cross between *S. scabies* strains *A*26–34 (nicotinic acid$^-$, biotin$^-$, tyrosinase$^-$, streptomycin sensitive) and *A*26–37 (arginine$^-$, methionine$^-$, tyrosinase$^+$, streptomycin resistant) the spores formed by the heterokaryon reproduced the two patterns of parental nutritional deficiencies in a ratio of about 50 : 1, respectively, although the ratio varied somewhat from experiment to experiment (Table 1). When platings were made from heterokaryotic colonies on to minimal medium, most of the few colonies which developed were found to be heterokaryons and may have developed from fragments of mycelium or might have arisen *de novo* from the two parental types present. When platings were made from heterokaryons on to nutritionally selective media, essentially all the colonies of both parental nutritional types gave a strong tyrosinase reaction, the incidence of tyrosinase-deficient colonies being no greater than that observed with normal tyrosinase-producing cultures.

Table 1. CYTOPLASMIC INHERITANCE OF TYROSINASE COMPETENCE VIA HETEROKARYON FORMATION

Medium	Counts per ml. of spore suspensions prepared from single colonies of:		
	*A*26–34	*A*26–37	Heterokaryon of *A*26–34 × *A*26–37
Minimal	0	0	$8\cdot8 \times 10^{2}$
Minimal + nicotinic acid + biotin	$4\cdot1 \times 10^{6}$	0	$3\cdot7 \times 10^{6}$
Minimal + arginine + methionine	0	$2\cdot2 \times 10^{6}$	$8\cdot1 \times 10^{4}$
Complete + streptomycin	0	$2\cdot0 \times 10^{6}$	$6\cdot2 \times 10^{4}$
Per cent tyrosinase-producing colonies	0	> 99	> 99

The reverse cross yielded similar results. Thus when strain *A*26–54 (nicotinic acid$^-$, biotin$^-$, tyrosinase$^+$, streptomycin resistant) was plated on minimal medium together with strain *A*26–53 (arginine$^-$, methionine$^-$, tyrosinase$^-$, streptomycin sensitive) and the resulting heterokaryotic colonies plated on nutritionally differential media, once again nearly all the colonies of both parental nutritional types were tyrosinase$^+$ (Fig. 1). The tyrosinase-producing abilities of colonies carrying the nutritional requirements of the formerly tyrosinase-deficient parents were shown to be perpetuated throughout at least six consecutive transfers on complete medium.

Many of the colonies developing on medium supplemented with nicotinic acid and biotin, from both crosses, required only nicotinic acid for growth. This acquisition of independence of biotin was considered to result from the relatively high frequency of back mutation to biotin$^+$ ($1\cdot6 \times 10^{-4}$ per parental spore plated) coupled with the fact that these back mutants made a greater amount of residual growth on the minimal medium than did the diauxotroph. There was thus an increased probability of heterokaryon formation with these biotin$^+$ back mutants. A selection of tyrosinase$^+$ back mutants during heterokaryon formation appears to have been highly unlikely since this back mutation has never been detected. Furthermore, the tyrosinase$^+$ characteristic gave this culture no apparent selective advantage on the media employed.

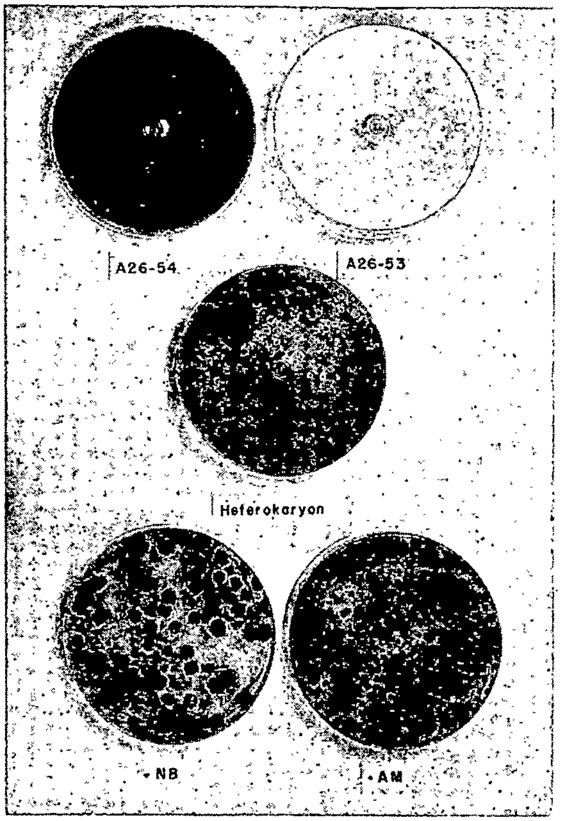

Fig. 1. Appearance of the under side of colonies of parental, heterokaryon and recovered parental nutritional types on tyrosine-containing media. Top: parental strains *A*26–54 (nicotinic acid$^-$, biotin$^-$, tyrosinase$^+$, streptomycin resistant) and *A*26–53 (arginine$^-$, methionine$^-$, tyrosinase$^-$, streptomycin sensitive) on complete medium. Centre: heterokaryons from the above strains on minimal medium. Bottom: colonies developing, from spores formed by heterokaryon, on minimal medium supplemented with nicotinic acid + biotin (+ *NB*) and arginine + methionine (+ *AM*)

Genetic recombination of the determinants for nutritional deficiencies and streptomycin resistance was detected by plating spores from heterokaryons on minimal medium containing various combinations of nutritional supplements and streptomycin. Excluding the nicotinic acid$^-$ biotin$^+$ streptomycin-sensitive class, which was not considered to arise by recombination, recombinants comprised only a small proportion (< 0·1 per cent) of the total spores formed by the heterokaryons. On the assumption that these characteristics were inherited as nuclear genes, it was apparent that the incidence of nuclear genetic recombination in these strains was not sufficient to account for the abundant coupling of tyrosinase-producing capability with the nutritional deficiencies of the formerly tyrosinase-deficient strains.

A selective overgrowth of the heterokaryon with recombinant nuclei containing the tyrosinase$^+$ determinant was improbable in view of the short interval available for such overgrowth (development of one colony), lack of a demonstrable selective growth advantage of this characteristic in the test conditions, and the clear demonstration in *Neurospora* that even nuclei bearing genes with a strong selective advantage did not increase in proportion during the growth of a heterokaryon[6]. Even if the large number of biotin$^+$ colonies produced by the heterokaryons had resulted from the formation, by recombination, of nuclei bearing this characteristic, followed by a selective increase in the proportion of this type of nucleus within the heterokaryon, the high incidence of tyrosinase$^+$ colonies obtained clearly would not have resulted from a close linkage of this determinant to the biotin locus, since most of the biotin$^+$ colonies from *A*26–53 × *A*26–54 heterokaryons would then have been deficient in tyrosinase.

The tyrosinase$^+$ colonies obtained from the heterokaryons were shown not to have been derived from multinucleate or diploid spores, since spores of these cultures showed an exponential rate of killing by X-rays, usually characteristic of a haploid, uninucleate condition, and the other genetic markers could not be recovered afterwards from these cultures. The culture from which these genetically marked strains were derived appeared cytologically to have a single nucleus[5].

Attempts to obtain infective transfer of tyrosinase-producing ability from *A*26–37 to *A*26–34 were unsuccessful. Culturing *A*26–34 in both liquid and solid media containing 10 per cent culture filtrate or a membrane-filtered extract of sonically disrupted mycelium of *A*26–37 did not result in a single tyrosinase-producing colony. The quantitative transfer of tyrosinase-producing ability from a tyrosinase-producing strain of *S. scabies* to a tyrosinase-deficient strain did not, therefore, appear to be mediated by a free virus like the carbon dioxide sensitivity factor in *Drosophila*[7], toxigenicity in *Corynebacterium diphtheriae*[8] or some antigenic changes in *Salmonella* spp.[8].

The phenomenon described here appears to be explained best by postulating the presence of autoreproducing constituents in the cytoplasm, which control the production of tyrosinase in this species. Strong evidence exists for cytoplasmic inheritance of several characteristics in diverse organisms[9]. Horowitz and Fling[10], however, specifically ruled out cytoplasmic inheritance of tyrosinase-producing ability in *Neurospora crassa* with data diametrically opposed to that presented here for *S. scabies*.

COMPARISON OF PYRIDINE NUCLEOTIDES IN THE LIVER AND IN AN ASCITIC HEPATOMA

By M. WINTZERITH N. KLEIN, L. MANDEL and PROF. P. MANDEL

Centre de Recherches Nucléaires, Applications Biologiques, Strasbourg-Cronenbourg, and Institut de Chimie Biologique, Faculté de Médecine, Strasbourg

THE work of von Euler[1] showed that there was no difference in the diphosphopyridine nucleotide (DPN) and triphosphopyridine nucleotide (TPN) contents of the liver, muscle and Jensen's sarcoma in the same animal. Since then, numerous data have accumulated showing that in tumours[2–5], in tumoural mitochondria[6] and in organs in a pre-cancerous state[7] the DPN content is lower than in normal tissues. In animals with a tumour such as sarcoma 37, a lymphoma or a hepatoma, a decrease in DPN of certain cells has been noted[8,9]. However, in most cases, the comparison between normal and neoplasmic tissues concerns cells the morphology of which differs widely. Furthermore, different types of cells contain varying amounts of DPN and TPN whether in normal or neoplasmic tissues.

These reasons prompted us to compare the DPN and TPN contents in normal liver, in the Zajdela hepatoma and in the liver of animals with this tumour. Here we are concerned with homologous types of tissues and with a tumour which has not lost as much of the character of the original tissue as sarcomas or Ehrlich ascitic cells which have been transplanted many times. The hepatoma of Zajdela which we utilize maintains the trabecular structure of liver parenchyma. This is important because hepatomas can originate in various liver cells: biliar-epithelium, parenchymatous cells, reticulo-endothelial cells, and a comparison between the liver and tumour will be valid only if the latter is also of a parenchymatous nature. Pitot and Potter[10] have emphasized recently the different biochemical characters of distinct morphological types of hepatoma. In our comparison of normal and tumorous tissues we have utilized various bases of references besides the wet weight normally used. In particular, we thought it interesting to compare values related to the deoxyribonucleic acid (DNA) content, thus obtaining an indication at the cell-level.

In our comparative experiments on the pyridine nucleotides of liver and hepatoma we used twenty standardized rats, eight being for estimations on the liver and twelve for the tumours. For investigating the effects of nicotinamide we used eighteen rats, ten of which had a tumour. Reduced diphosphopyridine nucleotide (DPNH), DPN and the total TPN +

reduced triphosphopyridine nucleotide (TPNH) were determined by the enzymic method described by Holzer *et al.*[11]. After fractionation according to Schmidt and Thannhauser[12], DNA was determined by the estimation of deoxyribose by the method of Dische[13] as modified by Burton[14]. Our experimental results are recorded in Figs. 1–3.

Fig. 1 shows that the presence of an ascitic hepatoma alters only slightly the DPN and TPN + reduced TPN contents of the liver. Although the values for animals with a tumour vary within narrower limits than in normal subjects and the average results are slightly higher in the controls, the differences are not significant.

Fig. 2 shows the DPN, reduced DPN and TPN contents of liver and ascitic cells. Bearing in mind the difficulty of accurate assessment of the wet weight of ascitic cells, we related our results to accurately determinable quantities, that is, dry weight, proteins and DNA. Our results demonstrate that the values of DPN related to dry weight are higher for the liver than for ascitic cells. The same applies for reduced DPN and the triphosphopyridine nucleotides as a whole. Even though the standard deviation for the results is comparatively high the difference is statistically valid. The average values for the DPN, reduced DPN and TPN + reduced TPN contents of tumorous tissues were, respectively, 61 per cent, 77 per cent and 55·5 per cent of the values for normal liver. The percentages are of the same order, if the results are related to proteins. The differences between normal and ascitic cells are more important and highly significant if the values are related to DNA. Thus, the average values for the DPN, reduced DPN and TPN + reduced TPN of ascitic cells are only 14·4 per cent, 17·6 and 12 per cent, respectively, of the values for normal tissues.

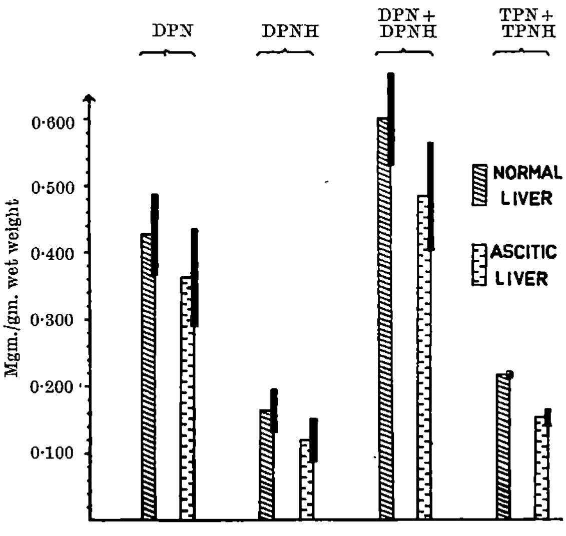

Fig. 1. Comparison of pyridine nucleotide content of normal liver and the liver of an animal with a Zajdela hepatoma

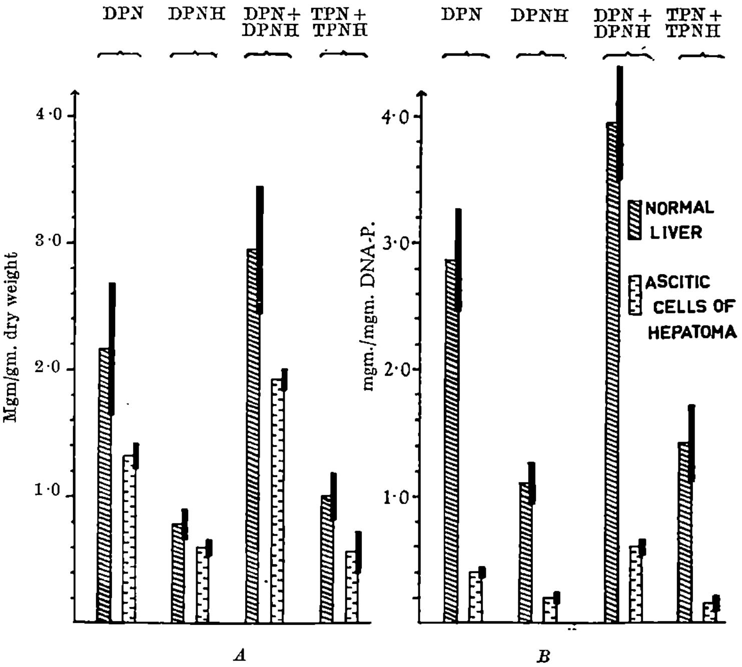

Fig. 2. Comparison of pyridine nucleotide content of normal liver and an ascitic heptoma. *A*, values expressed in mgm. per gm. dry weight; *B*, values expressed in mgm. per mgm. DNA-P. The nuclei of the hepatoma contain on average twice as much DNA as the nuclei of a normal liver

Under the influence of nicotinamide, DPN and reduced DPN increase at about 2–3 times the rate in normal liver as in ascitic cells, while the rate of increase of the triphosphopyridine nucleotides is about twice as great.

The presence of the hepatoma, while affecting the synthesis of ribonucleic acid and DNA of various tissues, as we have shown previously[15,16], does not cause an appreciable fall in the content of di- and triphosphopyridine nucleotides. However, the amounts of pyridine nucleotides in tumour cells retaining the structure of liver trabeculæ are considerably reduced. The most important differences are found at cell level, when referring the values to DNA. Since cell equilibrium can be expressed by the ratio cellular constituent/DNA it is evident that if the quotient, in our case pyridine nucleotide/DNA, is at all modified, it represents a disturbance of this equilibrium.

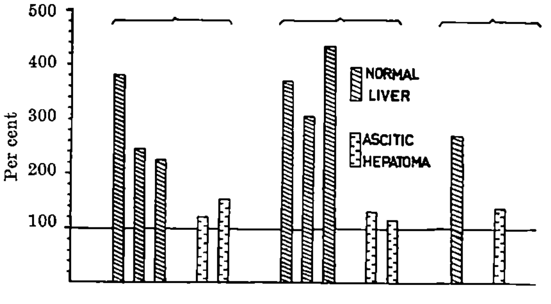

Fig. 3. Effect of injection of 50 mgm. of nicotinamide per 100 gm. wet weight, 8 hr. before killing, on the pyridine nucleotides of a normal liver and the cells of the ascitic hepatoma

The value of 100 was adopted for the controls. The height of the columns which extend above the horizontal line indicates, in per cent, the quantity of pyridine nucleotides in relation to the control

Finally, we find *in vivo* in a homologous tumour a considerable reduction in the net neo-synthesis of di- and tri-phosphopyridine nucleotides after the administration of nicotinamide (Fig. 3).

Summarizing, the reduction of the di- and tri-phosphopyridine nucleotides of an ascitic hepatoma of parenchymatous cells is noticeable when the values are referred to proteins or to the dry weight. The difference is all the more apparent when results are referred to DNA. The synthesis of di- and tri-phosphopyridine nucleotides, after injection of nicotinamide, is much inferior in hepatoma as compared to normal liver. No significant differences in DPN and TPN contents were found between normal liver and the liver of an animal with a hepatoma.

BIOCHEMICAL ASPECTS OF RESISTANCE TO 6-MERCAPTOPURINE IN HUMAN EPIDERMOID CARCINOMA CELLS IN CULTURE

By R. W. BROCKMAN, GEORGE G. KELLEY, PATRICIA STUTTS and VIRGINIA COPELAND

Kettering-Meyer Laboratory*, Southern Research Institute, Birmingham, Alabama

THE main pathway by which purines are metabolized to ribonucleotides is by the enzyme-catalysed reactions of the bases with 5-phosphoribosyl-1-pyrophosphate (PRPP) (refs. 1 and 2). Way and Parks[3], and Lukens and Herrington[4] demonstrated that purine analogues react similarly to form nucleotide analogues. A study of the purine ribonucleotide pyrophosphorylase capacity of enzyme preparations from *Streptococcus faecalis* and *L*1210 mouse leukæmia revealed that a specific decrease or loss of inosine 5′-phosphate (IMP) and guanosine 5′-phosphate (GMP) pyrophosphorylase activities accompanied resistance to 6-mercaptopurine (MP) and 8-azaguanine; enzyme preparations from the resistant cells also did not form 8-azaguanosine 5′-phosphate (azaGMP) and MP ribonucleotide in significant amounts[5-7]. Adenosine 5′-phosphate (AMP) pyrophosphorylase activity was not altered in these resistant cell lines.

The present work extends these observations to a human neoplasm in cell culture. The cell line used was the *H.Ep*-2 line derived from a human epidermoid carcinoma[8]; MP-resistant sub-lines of this were developed recently in this Laboratory[9]. The line was grown in static culture on glass and also in suspension culture[10,11]. The resistant sub-lines (*H.Ep*-2/MP) were isolated from clones that developed on glass in the presence of 0·5, 1 and 10 µgm./ml. of MP which, at a concentration of 0·5 µgm./ml., completely inhibited growth of the parent-sensitive line[9]. *H.Ep*-2 cloned in the presence of 1 and 10 µgm./ml. MP grew in suspension cultures in the presence of concentrations of MP as high as 320 µgm./ml. These sub-lines exhibited significant cross-resistance to 8-azaguanine.

The metabolism of purines and analogues was compared in the *H.Ep*-2 cell lines in suspension culture; the cell population per 100 ml. medium at the time of addition of tracer was 40×10^6 for *H.Ep.*-2/*S* and 20–30×10^6 for the MP-resistant sub-lines. The cells were incubated in the presence of the radioactive substrates for 24 hr., and then soluble extracts of the cells were prepared for two-dimensional paper chromatographic–radioautographic analysis by procedures previously described in studies with ascites tumour cells[5,6]. The residues from the alcohol extractions were treated with hot 10 per cent sodium chloride followed by precipitation of the nucleic acid fraction with ethanol[5,6]. The nucleic acid preparations thus obtained were examined spectrophotometrically and the optical density at the absorption maximum, 260 mµ, was used as a measure of the concentration of nucleic acid. The specific activity of the preparations was determined by evaporation of nucleic acid solutions of known concentration on planchets for counting in internal gas-flow proportional counters.

The results summarized in Table 1 show that adenine extensively labelled the nucleic acids of sensitive and resistant *H.Ep*-2 cells. Guanine, 8-azaguanine and hypoxanthine only labelled the nucleic acids of the sensitive cells. Azaguanine was shown to be incorporated into the ribonucleic acid (RNA) of *H.Ep*-2/*S* as azaguanlyic acid by procedures described by Matthews[12]. The *H.Ep*-2/*S* cells incubated in the presence of 6-mercaptopurine labelled with sulphur-35 were too weakly radioactive for the nature of the material containing sulphur-35 to be identified. Results of analysis of the soluble fractions from these cells showed that nucleotides of adenine but not of guanine, 8-azaguanine, hypoxanthine or 6-mercaptopurine were present in the MP-resistant cells. Conversion of adenine, hypoxanthine and 6-mercaptopurine to nucleotides was extensive in *H.Ep*-2/*S*; the soluble pools of nucleotides derived from guanine and 8-azaguanine were small but detectable.

Enzyme preparations were made from sensitive *H.Ep*-2 cells grown in suspension culture and also from suspension cultures derived from clones which grew in the presence of 0·5, 1 and 10 µgm./ml. of MP. Cells were separated from growth medium by

Table 1. RADIOACTIVITY OF NUCLEIC ACIDS FROM SENSITIVE AND RESISTANT HUMAN EPIDERMOID CARCINOMA CELLS GROWN IN THE PRESENCE OF LABELLED PURINES AND ANALOGUES*

Substrate	Specific activity of nucleic acids (counts/sec./mgm.)		
	H.Ep-2/*S*	*H.Ep*-2/MP †	
		1	10
Adenine-8-^{14}C	14,354	17,401	17,086
Guanine-8-^{14}C	1,551	5	2
8-Azaguanine-2-^{14}C	363	3	3
Hypoxanthine-8-^{14}C	9,991	3	4
6-Mercaptopurine-^{35}S	20	2	2

* *H.Ep*-2 cells were grown in suspension culture and incubated in the presence of radioactive substrates for 24 hr. The nucleic acids were isolated for quantitative determinations of radioactivity.

† The two different sub-lines of *H.Ep*-2/MP were isolated on glass by cloning in the presence of concentrations of 6-mercaptopurine of 1 and 10 μgm./ml., respectively.

centrifugation, washed with physiological saline, and re-suspended in cold 0·05 *M* sodium phosphate buffer, *p*H 7·5. The volume of buffer used was 1 ml. for each 4 × 10^8 cells. The resulting cell suspension was subjected to rapid freezing in an ethanol–dry ice bath followed by gradual thawing; this cycle was repeated twice more to effect disintegration of the cells. The resulting preparation was centrifuged at 95,000*g* for 90 min. at 4° C. in a Spinco centrifuge. The clear supernatant served as the crude enzyme preparation and was frozen and stored at − 15° C. Enzyme solutions thus prepared were analysed for protein by the Oyama–Eagle modification[13] of Lowry's method.

The reaction mixtures used in work on enzyme activities are described in Table 2; they were analysed by methods previously described[5-7]. The results show that enzymes from both the sensitive and the MP-resistant *H.Ep*-2 lines formed nucleotides from adenine, 4-aminopyrazolo(3,4-*d*)pyrimidine, 2,6-diaminopurine, and 4-amino-5-imidazolecarboxamide; in all cell lines the yield of AMP was very much greater than those of these other nucleotides. Conversion of xanthine to xanthylic acid was poor in the sensitive *H.Ep*-2 and was decreased in the MP-resistant lines. Hypoxanthine, MP, guanine, and 8-azaguanine were converted to nucleotides in good yields by enzymes from sensitive cells; yields of these nucleotides with identically prepared enzymes from MP-resistant cells were much lower and in some instances negligible. A decreased capacity for formation of these four nucleotides was evident in all the resistant lines, even in the line cloned in the presence of 0·5 μgm./ml. MP. However, there was some evidence for slight additional loss of capacity in lines cloned at higher concentrations of MP. The cell line cloned in 10 μgm./ml. MP was grown in the absence of MP for 60 generations (*H.Ep*-2/10-MP), after which the loss of enzymic capacity was still essentially complete. This result indicates that resistance to MP probably arose by mutation in the human tumour cell lines, as in other biological systems. The specific loss of IMP and GMP pyrophosphorylase activity in *H.Ep*-2/MP resulted in loss of capacity of the growing cells to form nucleotides of these bases or to incorporate guanine, 8-azaguanine or hypoxanthine into nucleic acids.

The specificity of action of the purine ribonucleotide pyrophosphorylases of *H.Ep*-2 is also of interest. IMP and GMP pyrophosphorylase activities were lost simultaneously, as was the case in MP- and azaguanine-resistant *S. faecalis* and *L*1210[5-7]. This is further evidence that a single enzyme or enzymes closely related genetically[14] may be responsible for this conversion. As in other systems[6,7] MP and azaguanine are evidently metabolized to nucleotides in *H.Ep*-2 by the IMP–GMP pyrophosphorylase enzyme system. Flaks, Erwin and Buchanan[15] observed that 4-amino-5-imidazolecarboxamide and adenine were converted to ribonucleotides by the same pyrophosphorylase. Results of the study of Roy, Haavik and Parks[16] showed that 4-aminopyrazolo(3,4-*d*)pyrimidine and adenine were also converted to ribonucleotides by the same pyrophosphorylase. (These workers found that 20-fold purified AMP pyrophosphorylase from beef liver was active in catalysing reactions of PRPP with 4-aminopyrazolo(3,4-*d*)pyrimidine, 2-fluoro-adenine, 2-aza-adenine and 8-aza-adenine.) Results of the present work are compatible with these results and suggest that in *H.Ep*-2 cells adenine, 4-aminopyrazolo(3,4-*d*)pyrimidine and 4-amino-5-imidazolecarboxamide are acted on by AMP pyrophosphorylase which is clearly distinct from IMP–GMP pyrophosphorylases. (Growth of MP-resistant *H.Ep*-2 cells was inhibited by 4-aminopyrazolo(3,4-*d*)-pyrimidine. Similarly, Skipper *et al.*[17], and Venditti, Frei and Goldin[18] observed that growth of 8-azaguanine-resistant *L*1210 tumours was inhibited by 4-aminopyrazolo(3,4-*d*)pyrimidine; this resistant neoplasm also retained AMP pyrophosphorylase activity while showing significant decreases in IMP–GMP pyrophosphorylase activities[5,6].) Similarly, Lieberman and Ove[19] studied resistance to purine analogues in mammalian cells in culture and observed that a 2,6-diaminopurine-resistant sub-line showed specific

Table 2. CONVERSION OF BASES TO RIBONUCLEOTIDES BY PYROPHOSPHORYLASES FROM 6-MERCAPTOPURINE-SENSITIVE AND -RESISTANT HUMAN EPIDERMOID CARCINOMA (*H.Ep*-2) IN CELL CULTURE

Ribonucleotide formed	mμmoles ribonucleotide formed per mgm. protein in 1 hr. *				
	H.Ep-2 (sensitive)	MP-resistant *H.Ep*-2 †			
		0·5	1·0	10	10-MP ‡

8-Azagunaylic acid	243	5	7	6	1

* The reaction mixture consisted of base (0·0005 *M*; 0·2 μc. per ml.), magnesium PRPP (0·002 *M*), and enzyme (approximately 200 μgm. of protein per ml. incubation mixture) in 0·1 *M tris* buffer, *p*H 7·6. Incubation time was 1 hr. at 37° C.; enzyme action was stopped and reaction mixtures deproteinized by heating for 5 min. at 100° C. Aliquots (0·1 ml.) were analysed by descending chromatography on Whatman 3 *MM* paper using 70 per cent *iso*propanol in an ammonia atmosphere to separate bases from the corresponding ribonucleotides. Radioactive areas of chromatograms located by radioautography were eluted with water; the eluates were evaporated on steel planchets and quantitative determinations of radioactivity were made by counting in gas-flow proportional counters. For identification purposes bases, ribonucleosides and ribonucleotides were separated and identified by two-dimensional chromatography and by paper electrophoresis using techniques already described (refs. 5–7).

† Concentration of MP (μgm./ml.) in which cell lines were originally cloned and isolated on glass. The clones developing in 0·5, 1·0 and 10 μgm./ml. of MP were subcultured in the presence of these concentrations of MP, forming confluent monolayers of cells. These resistant cell lines were then grown in suspension culture to provide material for enzyme preparations.

‡ *H.Ep*-2/MP cloned in 10 μgm./ml. of MP was resistant to concentrations of MP approaching the solubility limit of the inhibitor (320 μgm./ml.). This line was then grown in the absence of MP for 60 generations, after which enzyme preparations were then assayed for purine ribonucleotide pyrophosphorylase activity with the results shown in this column.

loss of AMP pyrophosphorylase activity; they suggested that 2,6-diaminopurine was anabolized by AMP pyrophosphorylase. This would also be consistent with the results obtained here with *H.Ep*-2.

Decreased activity of enzymes involved in the formation of nucleotides has now been observed to accompany the development of resistance to purine analogues in a variety of biological systems. Similar observations have been made in studies of resistance to pyrimidine analogues in both mammalian cells[20-23] and in micro-organisms[24,25]. Such alterations of enzyme activities may be of genetic origin since in many cases these losses have been demonstrated to be stable heritable characteristics of the resistant cells. The development of resistance to metabolite analogues is a serious problem in the therapy of neoplastic diseases[26], and an understanding of the nature and mechanism of the biochemical changes leading to resistance to metabolite analogues poses fundamental questions in areas of enzymology and biochemical genetics.

LIMITS OF HUMAN VISION

By Dr. R. A. WEALE

Department of Physiological Optics, Institute of Ophthalmology, Judd Street, London, W.C.1

FUNDUS reflectometry provides a means for studying the properties of visual pigments in the living eye. Whereas the detection of cone pigments is easy[1,2], the study of the human extra-foveal regions is complicated by their mixed receptor population. A detailed study of these regions[3] has shown that the unequivocal separation of rod and cone effects from each other is unlikely to be achieved without a close examination of difference spectra[4]. However, in the green region of the spectrum (510–520 mμ), where bleaching the dark-adapted eye with white light produces a maximum density difference, $\Delta D_{\lambda\,\mathrm{max.}}$, the effect of rod visual purple may be presumed to be dominant. If the bleaching intensity is expressed in the same units in which the absolute threshold is measured in stated conditions, an attempt to correlate the two types of measurement becomes feasible, all the more so as one is dealing with one species only, namely, man.

The latest model of the fundus reflectometer[2] was used, two retinæ being examined at locations shown in Table 1. Dark-adaptation preceding bleaching measurements always continued for 20 min., but 30 min. in the absolute threshold measurements. The bleaching exposure lasted 30 sec., the intensity being varied as shown along the abscissa (Fig. 1). The threshold measurements involved a criterion of 50 per cent 'seen' of the bleaching light, exposed for 0·036 sec. and reduced from 3 to 1·7° angular diameter.

The changes in density, $\Delta D_{\lambda\,\mathrm{max.}}$, are plotted on a percentage basis (Fig. 1) as a function of bleaching intensity. The maximum values corresponding to each subject and the retinal positions are shown in Table 1 and represent values for double transit through the retina. $\Delta D_{\lambda\,\mathrm{max.}}$ rises with intensity to a maximum at log scotopic trolands = 6·5.

A comparison of the bleaching and threshold data with work of Aguilar and Stiles[5] is of interest. These workers measured accurately the incremental threshold of rods (ordinate) as a function of adapting field luminance (abscissa). Their mean curve is reproduced in Fig. 1. The average of the present threshold measurements agrees with theirs as well as can be expected in view of the difference between the experimental conditions. But the following is the focal point of interest in the comparison. Aguilar and Stiles estimate that, in the region indicated with the arrowed bracket, human rods are saturated. This is to say, no matter how great the field intensity, the increment required to make the test visible approaches infinity. They calculate that this saturation is unlikely to be

Table 1. Maximum Values Corresponding to each Subject and Retinal Positions*

13° *T* ret.	0·125	▽	0·130
17° *T* ret.	0·085	▲	0·157

* This refers to Fig. 1.

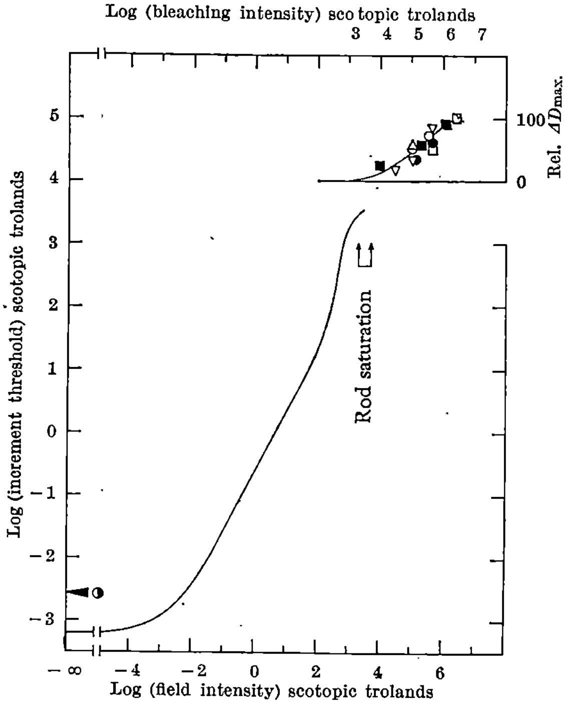

Fig. 1

due to the exhaustion of visual purple. The present results bear out this expectation: in the region of rod saturation the amount of pigment bleached becomes just measurable and is exhausted only at intensities nearly one thousand times as high.

The present results can be related to the absolute threshold in another way. Pirenne has shown in a very interesting paper[6] that visual purple would be expected to bleach at the rate of 1 per cent/sec. when the bleaching intensity is 10^{10} threshold. At first sight the results shown in Fig. 1 appear to contradict this prediction, such a bleaching rate occurring at about 10^7 threshold. But the following argument shows that the present results do, in fact, come close to Pirenne's prediction that the threshold and the rate of bleaching can be related along the lines which he suggested.

Let Q be the number of quanta absorbed at the absolute threshold; t, the time of exposure of the threshold test-light; A, its angular area in square degrees; N, the number of rods per square degree[6]; ν, the number of chromophores per rod[6]; α, the effective percentage absorption of the visual pigment[6], p, the fraction of pigment bleached in T, the bleaching time; R, the ratio (the energy flux per unit time bleaching p per cent of pigment) ÷ (the flux producing the threshold response); γ, the quantum efficiency (number of chromophores bleached ÷ quanta absorbed); D, the orientation factor[8]; then:

$$p = \frac{RTQ\gamma D}{\alpha ANt\nu}$$

The following are among important assumptions in the derivation of this expression: absorption leads to bleaching; the amount bleached is such as not to change the absorption to a very marked extent (a proviso obeyed approximately in present conditions when $p = 0 \cdot 2$); in the conditions of the experiment, the quantum efficiency is approximately 0·5 (refs. 4, 7); blinking[9] is not very important. Denton[8] has shown that the absorbing molecules are so positioned as to render absorption maximal when the light travels along the axis of the rod. It is doubtful whether this can apply in all rigour to the human eye, the rods pointing approximately at the posterior nodal point, and it will apply with even less certainty to light re-traversing the retina after reflexion from the fundus. But accepting a value of $D = 1 \cdot 5$ for this effect and a quantum efficiency of $\gamma = 0 \cdot 5$, the number of chromophores ν has to be multiplied by 1·33. Substitution of experimental values in the equation leads to $Q = 7–14$ if some uncertainty in the results is allowed for. The calculated value yields a result of the order of magnitude obtained by other methods[6]. Although ν, the number of chromophores per rod, was calculated on the basis of frog visual purple data[6], it is unlikely that comparably accurate data for human visual purple would affect the situation very much[10].

An increase in bleaching intensity beyond that shown in Fig. 1 leads to an unexpected result. The change in density recorded for the wave-length of maximum change is smaller at the highest intensity used (cf. Fig. 2) than it is at the top intensity shown in Fig. 1. This finding appears to hold for both extra-foveal and foveal parts of the retina. Control of the pupil diameter[3,11] reduces the likelihood of miosis of the strongly mydriaticized iris being responsible for this effect in intense illumination. An extension of the recording of changes of density to the whole of the visible spectrum shows that the apparent reduction in $\Delta D_{\lambda\max.}$ is due to an upward move of the whole base-line, a finding which can be pictured by the hypothesis that, in very intense illumination, a grey filter is formed in the eye. The effect disappears after dark-adaptation for 3 min. An early stage in thermal lesions, known to lead to retinal œdema, is manifested by a greying of the fundus oculi. The view that the rise in the zero line mentioned above is an even earlier manifestation of such a process is supported by radiometric measurements of the intensity of the bleaching light (top of Fig. 2). These

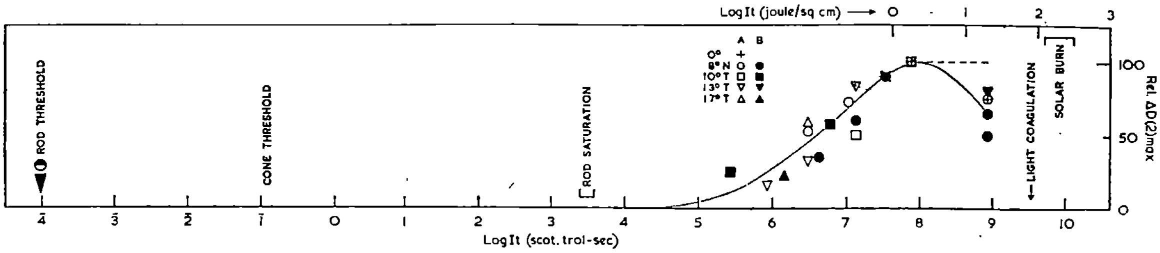

Fig. 2. Ordinate: Relative values of maximum change of density (double transit through retina) in various locations of two dark-adapted human retinæ A and B (see inset). Abscissa: bleaching intensity × exposure time in scotopic trolands × sec. (bottom); in joules/sq. cm. on the retina (top). Free-hand curve. Effects due to blinking and absorption in pre-retinal media are neglected. The rod threshold was measured on subjects A and B (cf. Fig. 1). The broken line represents the function of $\Delta D(2)_{\max.}$ when the œdema effect is compensated

relate the present results to exposures causing solar burns[12], just as an extension of the photometric scale (bottom of Fig. 2) relates them to exposures leading to light-coagulation[13]. It may be suggested tentatively that the constitution of human retinal light-sensitive material is such that the lower limit of the visual range is governed by quantum physics, whereas the upper limit coincides with the safety-level of ocular tissues exposed to thermal hazards.

PHOSPHATASES IN *SCHISTOSOMA MANSONI*

By Dr. D. L. H. ROBINSON
Medical Research Council Group for Research in Bilharzia, Winches Farm, St. Albans

Distribution of Alkaline Phosphatase

DUSANIC[1] made a histochemical study of alkaline phosphatase in larval and adult *Schistosoma mansoni* and tissues associated with these stages in both molluscan and final hosts. In adult flukes the enzyme was found in the subcuticular cells, the mesenchyme, the ovaries, testes and the intestinal cells. High concentrations of the enzyme were found in the intestinal cells, and in the ovaries and testes alkaline phosphatase activity was considerably greater than in the mesenchymal cells.

During an examination of the methods of carbohydrate uptake in schistosomes, I investigated the distribution of alkaline phosphatase in *S. mansoni*. Mature flukes were obtained from the portal and mesenteric veins of hamsters 8–10 weeks after infection with 150 cercariæ of an Egyptian strain of the schistosome maintained in a Puerto Rican strain of *Australorbis glabratus*. After a quick rinse in cold saline, the worms were transferred as rapidly as possible to ice-cold acetone. Alkaline phosphatase activity was determined by Glick's[2] modified Gomori method using a sodium glycerophosphate substrate. Sections cut in both longitudinal and transverse planes at 10μ were incubated at 37° C. for 1 hr., this time having been arrived at by the method of Martin and Jacoby[3]. Control slides, incubated without substrate, were negative.

Fig. 1 shows part of a transverse section of a male *S. mansoni* in the region of the testis. High alkaline phosphatase activity is present in the subcuticular cells and in the mesenchyme, but considerably less in the testis. The black deposit in one of the cæcæ in Fig. 1 is due to pigment in the lumen, but the intestinal cells show little activity except for the nuclei. Similar results were obtained in the intestinal cells of female worms and the ovaries exhibited lower activity than the mesenchyme.

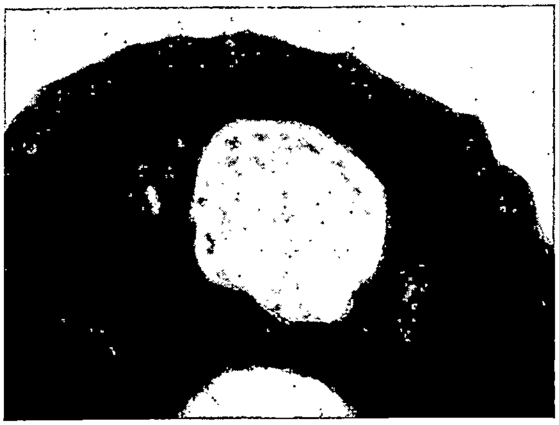

Fig. 1. Portion of a transverse section of a male *Schistosoma mansoni* showing distribution of alkaline phosphatase

There appears to be abundant evidence available to confirm the view of Rogers[4] that regions exhibiting high alkaline phosphatase activity might be associated with carbohydrate absorption. Based on this hypothesis, the results given above, in contrast to those of Dusanic[1], suggest that the major region of carbohydrate uptake from the environment in *S. mansoni* is the cuticle, with the intestinal cells playing a secondary, if not a minor part.

Quantitative Estimation of Phosphatases

HISTOCHEMICAL examination shows that high alkaline phosphatase activity is present in *Schistosoma mansoni* at *p*H 9·4. Dusanic[1] observed that the alkaline phosphatase had a *p*H optimum of 9·0–9·5, and exhibited only slight activity at *p*H 8·6. At *p*H 8·0 no activity could be detected by histochemical methods.

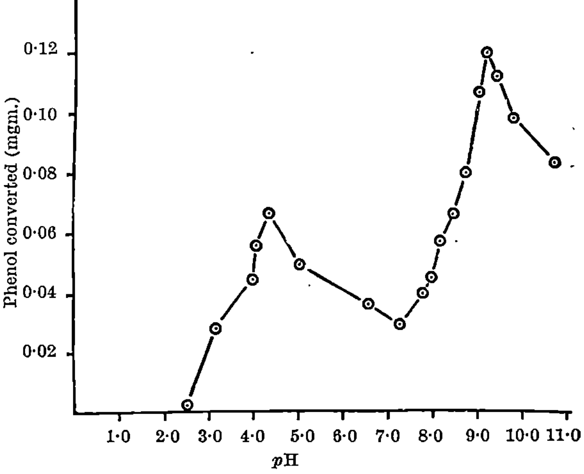

Fig. 2. Phosphatase activity of extract of male *S. mansoni* at different hydrogen ion concentrations. 130 worms, extract made up to 25 ml. Incubation time, 18 hr.

The quantitative experiments reported here were performed: (a) to determine the *p*H optima of the alkaline phosphatase of *S. mansoni*; (b) to demonstrate an acid phosphatase if one were present; (c) to compare the activity of these enzymes, at different hydrogen ion concentrations.

Mature schistosomes were removed from the portal veins of hamsters infected 8 weeks previously with *S. mansoni*. Pairs were separated and male and female worms counted and ground separately in a glass tube containing distilled water. Toluene was then added and the mixture allowed to stand on the bench for 4–5 hr. After centrifugation the supernatant was stored overnight in the refrigerator. The solution was diluted immediately before use.

Incubation mixtures consisted of 1 ml. substrate, 1 ml. extract, 1 ml. buffer and 0·5 ml. toluene. The buffers used were acetate/barbiturate/hydrochloric acid (Michaelis 1931) and glycine/sodium hydroxide (Sorensen Walbum, 1920), and the substrate was 0·01 *M* disodium monophenyl phosphate. The *p*H of each mixture was determined, before and after incubation, on a Pye *p*H meter. After incubation, aliquots were removed for estimation of the phenol liberated, by the method of King and Armstrong[5], using the reagent of Folin and Ciocalteau. Controls consisted of unincubated mixtures, and the results were deducted from those of the test.

An alkaline and an acid phosphatase were present in male and female worms. No sex differences were observed in their characteristics. The alkaline phosphatase had its optimum in the region of *p*H 9·3 and the acid phosphatase had an optimum in the region of *p*H 4·4. As can be seen from Fig. 2, the alkaline phosphatase exhibited the higher relative activity.

Bueding[6] found that carbohydrate uptake in *S. mansoni* amounted to the equivalent of one-fifth of its dry weight per hour. The high alkaline phosphatase activity reported above may therefore be linked with this high carbohydrate uptake and adds further support to the view of Rogers[4] that regions of high alkaline phosphatase activity are associated with carbohydrate absorption.

SOCIAL DOMINANCE IN INBRED MOUSE STRAINS

By PROF. G. LINDZEY, H. WINSTON and M. MANOSEVITZ

Department of Psychology, University of Minnesota, Minneapolis 14

ORIGINS of the experimental study of temperament in lower animals[1–3] are approximately as remote as origins of the experimental study of learning in lower animals[4,5]. In spite of this historical similarity the two domains to-day are dramatically different in their respective achievements. By almost any reasonable criterion the area of learning has attained a state of maturity far surpassing that of research in animal temperament. While there are undoubtedly many factors that have contributed to this relative deficiency in investigation of animal temperament, one of the most important of these is the absence of a set of sensitive and reliable measures that can be used to assess variables commonly viewed as significant or interesting.

This article is presented as a very small corrective to this deficiency. It describes a measure of social dominance and presents tentative results, based on the comparison of three inbred strains of mice, suggesting that the test possesses reasonable sensitivity and stability. For present purposes we may define social dominance simply as the tendency of an animal to make a goal response when this response involves overcoming the competing response of another animal similarly motivated.

The subjects in this work consisted of 44 animals in each of three inbred mouse strains. Breeding stock for each of the strains was obtained from the colony maintained by Prof. John Bittner in the Department of Cancer Biology at the University of Minnesota. Mice within each strain have been bred by brother–sister mating well beyond the twenty generations that are conventionally believed to lead to offspring that are approximately homozygous. The three strains and the number of generations of inbreeding are as follows: *A*/alb (57), *C3H* (97), *DBA*/8 (28). The subjects were at least 60 days old, and animals that were opposed to each other were matched in age and sex. All animals were individually housed after weaning at 22 days of age.

The dominance test consists of a 'Lucite' tube, 1 in. inside diameter and 17 in. long. The tube is connected at each end to a goal box that is 4 in. × 4 in. × 2 in. and covered by a wire cloth top. Guillotine doors are located at the entrance to each goal box and a small 'Lucite' divider can be inserted midway in the tube. The diameter of the tube is just sufficient to permit a mature mouse to pass through it readily, but not sufficient to permit two mice to pass one another in the tube. It should be mentioned that although this technique was devised in our laboratory, after we had worked with it for a period of time, we learned that Prof. Tsai of Tulane University had used a similar apparatus with rats. Each animal was given a series of five training trials on each of three successive days. The animals were run, deprived of food (85 per cent of normal weight) with the reward of wet mash in the goal box after they had passed through the tube. During the training trials the mice were alternated in the direction that they ran through the tube and the experimenter recorded the time required to reach the goal box on each trial. Following this, there was a period of five dominance test days on each of which the animals received individually three further training trials before the test trials.

On a dominance trial the mice were placed at the same time in two goal boxes at the entrances to the tube and when they had both reached the centre of the 'Lucite' tube the divider was removed and the issue was joined. The trial ended when one mouse had forced the other to retreat with all four feet into the goal box from which it had commenced. The order of the various oppositions within each group, and the goal box in which each mouse began, were systematically varied on successive days. The animals were deprived of food during all the test trials.

Mice were run in groups of four. Each group included two animals from two of the three strains under investigation and each mouse opposed every other mouse in his group on each of the five test days. Thus, there were eleven groups involved in each of the three strain comparisons (*A*/alb versus *C3H*, *A*/alb versus *DBA*/8, *C3H* versus *DBA*/8). We were interested in differences of strain and for each mouse there was a dominance opposition to two mice from the other strain on each test day, or a total of ten such oppositions per mouse by the end of the test series.

The simplest and most meaningful indexes of *stability* consist of the proportion of mice that achieved dominance by winning all five of their trials, the proportion that achieved dominance by winning four out of five trials, and the proportion that won three out of five trials. In the opposition between *A*/alb and *C3H* mice, 57 per cent of the dominant mice won all five trials, 27 per cent won four trials, and 16 per cent won three trials. In the opposition between *A*/alb and *DBA*/8 mice, 75 per cent of the dominant animals won all five trials, 20 per cent won four trials, and 5 per cent won three trials. In the opposition between *C3H* and *DBA*/8 mice, 64 per cent of the dominant animals won all five trials, 18 per cent won four trials, and 18 per cent won three trials. If we combine the results for all strain comparisons, we find that in approximately two-thirds of the cases, there was complete consistency, with the same animal winning all five of the trials. In slightly more than one-fifth of the oppositions the dominant animal won four out of the five trials, and in less than one-eighth of the cases the dominant animal won only three out of the five trials. In general, the consistency across repeated trials of the test was so marked that, knowing the performance of a particular pair of mice for a single trial, provides an excellent basis for predicting the outcome of the four subsequent trials.

The matter of *transitivity* is somewhat more difficult to represent although the results for strain comparisons are obvious. There is complete transitivity between strains, for example, *A*/alb > *C3H*, *C3H* > *DBA*/8, *A*/alb > *DBA*/8; moreover, the fact that the superiority of the *A*/alb over the *DBA*/8 is greater than the superiority of the *A*/alb over the *C3H* is reflected in the dominance of the *C3H* strain over the *DBA*/8 strain. Nevertheless, there are so few strain comparisons possible in our work that this is not altogether a satisfactory measure.

An index of transitivity between individual animals was devised that could be applied to each group of four animals. A group was declared transitive if it arranged itself in an hierarchical manner, so that the most dominant subject dominated all other animals, the second most dominant animal dominated all animals except the most dominant, and so on. Using this procedure there were a total of 33 such groups and all but two met this stringent criterion of transitivity. Thus, our evidence suggests a high degree of transitivity in the dominance relations of individual animals as well as in the relations between strains.

Table 1. STRAIN DIFFERENCES IN DOMINANCE

	A/alb versus *C3H*		*A*/alb versus *DBA*/8		*C3H* versus *DBA*/8	
Per cent of total trials dominant *n* (animals) = 22 *n* (observations) = 220	78	22	94	6	78	22
Per cent of total pairings dominant *n* (animals) = 22 *n* (observations) = 44	84	16	98	2	82	18
Per cent of animals winning more than one-half of the oppositions with other strain *n* (animals) = 22 *n* (observations) = 22	86	14	100	0	86	14

Previous investigators who have been concerned with measuring dominance in animals have not, for the most part, concerned themselves with the reliability or transitivity of their measures. Those investigators who have inquired into those questions[6-8] have reported results indicating much less stability than we have observed.

The results summarized in Table 1 leave no doubt about the existence of *differences between strains* in performance on this test. The results of the strain oppositions are summarized by means of three correlated indexes that are completely consistent in the direction and the magnitude of the results they depict. Perhaps the most revealing of these indexes is the third, which summarizes the number of animals within each strain that won more than half of their trials against animals from the comparison strain. The results indicate that 86 per cent of the *A*/alb mice won more than half of their oppositions against the *C3H* mice, 100 per cent of the *A*/alb mice won more than half their oppositions against the *DBA*/8 mice, and 86 per cent of the *C3H* mice won more than half of their oppositions against the *DBA*/8 mice. Thus, animals in the *A*/alb strain are dominant over animals in the *C3H* and *DBA*/8 strains and animals in the *C3H* strain are dominant over animals in the *DBA*/8 strain. Moreover, even given the genetic diversity of these strains, the magnitude of these differences is unusually large when compared with results obtained with other behavioural measures.

Results of this nature obviously suggest the importance of gene factors in determining dominance behaviour as we have measured it. There seems little doubt that a considerable proportion of the variance in our measure can be attributed to variation in genetic factors. These results are consistent with those reported by Ginsburg and Allee[9] on the basis of observing fighting behaviour in different strains. Uyeno[10], using a food competition measure of dominance, in conjunction with a single generation of selective breeding, also found evidence for the contribution of gene factors to dominance behaviour.

A further result of such a clear-cut differentiation between strains is some increase in our confidence in the measure we are employing. In other words, when subjects known to be quite distinctive in behaviour[11,12] are compared in terms of a particular measure, our interest in this measure is considerably dampened if it proves unable to discriminate between these distinctive organisms. Conversely, when the test can discriminate among subjects with unusual effectiveness, our confidence that the test is measuring something significant is increased.

Given that we have a measure that is rationally linked to dominance, and that it differentiates successfully between subjects that are known to be different in behaviour, there still remain many alternative explanations to be explored before we can be content with the label we have attached to the measure. For example, one might reason that the differences we have observed between strains are attributable to some simple, extraneous factor that may be genetically controlled and at the same time serves to influence performance on this test. It may be, for example, that the strains differ widely in weight so that even when animals are matched in age and deprivation experience certain strains will have an appreciable advantage in weight, and this difference will determine the result of the test procedures. This possibility was explored both within strains and between strains and we found no evidence for an association between weight and dominance. A second alternative hypothesis suggests that the strains may differ in the effectiveness with which they learn the original task involving passage through the tube and, consequently, they may be differentially motivated when placed in opposition in the tube. This possibility was examined by relating performance during the training trials (average time per trial) to performance on the dominance measure, but again we found no evidence of any association between the two variables. Thus, two of the most evident means of weakening the inferential link between the concept of dominance and our measure were found to be inconsistent with available evidence.

It is obvious that future investigations exploring the relation between the present measure of dominance and other measures of the same variable are very much needed. Our preliminary results indicate important differences in the results obtained with our measure and with the food competition measure employed by Rosen[13] and Uyeno[10]. It is also important that the relation between dominance and such related temperament variables as aggression and fearfulness should be explored. Given the results of such research, in addition to more detailed information concerning the determinants of performance on our measure, it should be possible to arrive at a meaningful estimate of the significance of this device for the student of animal temperament.

This work was supported by a grant from the Ford Foundation and Research Grant *M*-3536 from the National Institute of Mental Health of the National Institutes of Health, U.S. Public Health Service.

SIGNIFICANCE OF THE ANTI-SPORULATION EFFECT OF COPPER FUNGICIDES IN THE CONTROL OF SIGATOKA DISEASE OF BANANAS CAUSED BY *MYCOSPHÆRELLA MUSICOLA* LEACH

By E. EVANS, H. L. S. BEVINGTON and E. P. WHITAKER

Fisons Pest Control, Ltd., Chesterford Park Research Station, Nr. Saffron Walden

It is now a well-established belief that all copper fungicides are protective in function when used for the control of plant diseases. As such, an attempt is always made to cover the most susceptible parts of the host plant with a layer of chemical prior to the onset of the disease epidemic. This was the standard practice for the control of Sigatoka disease of bananas in most parts of the world until the introduction of eradicant oil spraying in 1956[1]. Bordeaux mixture is still being used in many parts of the world, but this practice is gradually becoming less economic. Accordingly, attempts have been made to introduce the ultra-low-volume application of copper fungicides from the air and from ground machines.

For the past six years we have been closely associated with the aerial application of copper fungicides to a number of crop plants, more particularly to potatoes and bananas. During visits to the field in West Africa and Central America, as well as from greenhouse studies in the United Kingdom, it has become obvious that the banana plant has unusual physical characteristics from the point of view of the retention of spray droplets. Leach[2] has shown that the spike, first and second open leaves are those most susceptible to leaf spot, yet a simple survey of any air-sprayed area of bananas shows quite clearly that these are rarely adequately covered with chemical. One of the main reasons for this phenomenon appears to be the highly reflective characteristics of these leaf surfaces as well as the exceptionally rapid development of the spike leaf during the main growing season.

From observations such as these it seems reasonable to suggest that any aerial application of a protective fungicide would not be particularly successful in controlling the disease unless such a chemical also acted by some other mechanism. One obvious alternative would be an anti-sporulation effect[2].

By courtesy of the United Fruit Co., laboratory facilities were made available in 1960 to two of us at Palmar Sur in Costa Rica (E. E., H. L. S. B.). During this visit an attempt was made to evaluate a number of standard fungicides as anti-sporulants, using a modification of the method recommended by R. W. Fulton (personal communication). Basically, this consisted of collecting leaf segments from the field, with Sigatoka lesions at the correct stage of

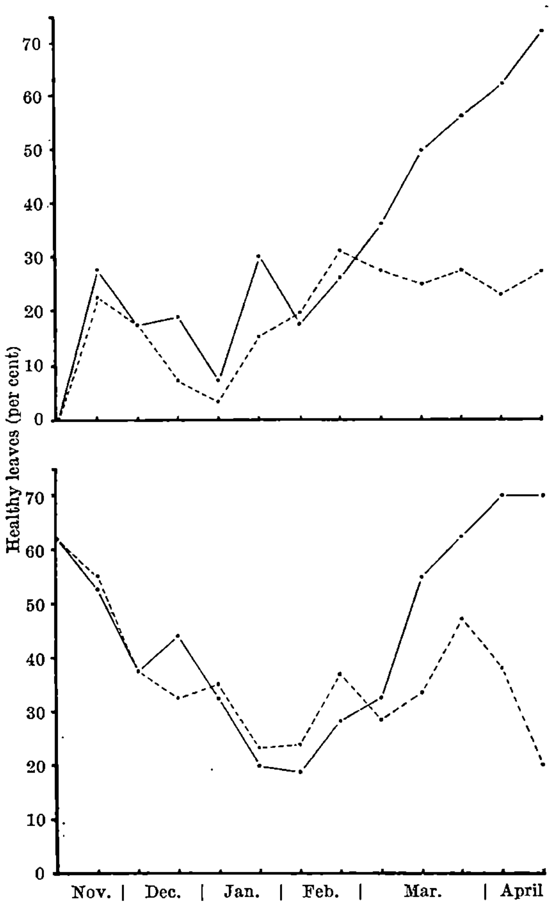

Fig. 1. Percentage of clean and lightly infected leaves in treated and untreated plots on parent (above) and follower (below) plants in a mature stand of bananas. ——, copper oxychloride; – – –, untreated control

development, spraying these lesions with the test chemicals and incubating for 24 hr. at 26° C. prior to examination under a stereoscopic microscope. The evaluations were made by comparing the number of sporulating lesions in the treated samples with those in the untreated controls. Sample data obtained in this manner are given in Table 1.

Table 1 shows quite clearly that standard fungicides such as copper oxychloride, zineb and a mixture of these two preparations have a marked effect on conidial production of lesions of *Mycosphærella musicola*. Since any lesion which produced a single recognizable spore was classified as a sporulating lesion, the results vastly under-estimate the total reduction of spores produced by the treated over the untreated lesions.

At the same time as these experiments were being carried out in Costa Rica, one of us (E. P. W.) was carrying out small-scale low-volume field trials on Gros Michel bananas in the Southern Cameroons. Here two experiments were attempted: site 1 on heavily infected mature banana plants; site 2 on a banana abandonment which was completely cut down then sprayed regularly during regrowth.

Table 1. ANTI-SPORULATION EFFECTS OF CERTAIN STANDARD PROTECTIVE FUNGICIDES

Chemical	Rate of application equivalent of four cycles/treatment at	Mean sporulating lesions after treatment (per cent)
Copper oxychloride	3½ lb. in 1–2 gal./acre	28
Zineb	2 lb. in 1–2 gal./acre	17
3:1 mixture of copper oxychloride and 'Zineb'	3 lb. in 1–2 gal./acre	5
Untreated control	—	79

Application of chemicals to both sites was made at 14-day intervals with a Kiekins Deckar Motoblo machine applying 3½ lb. of copper oxychloride per acre in 1 gallon of water containing 4 per cent v/v amine/stearate formulant[5]. The experiments were commenced in November 1959 and disease recordings were made at two-weekly intervals on one site until the end of April. The technique of recording used was a modification of that suggested by Leach[2]. On site 1 a sample of ten parent plants and ten followers were recorded on each occasion. On site 2, however, two separate samples of 15 plants each were recorded during the final examination, and the results obtained in this manner are summarized in Fig. 1 and Table 2 respectively.

Table 2. PERCENTAGE OF LEAVES RECORDED IN EACH DISEASE CATEGORY ON TREATED AND UNTREATED PLANTS DEVELOPING ON AN AREA THAT HAD PREVIOUSLY BEEN 'CUT DOWN' (SITE 2)

Treatment	Disease category	Samples 1	Samples 2
3½ lb. copper oxychloride in 1 gal./acre*	Nil	56·4	56·4
	Light	15·4	21·4
	Medium	26·5	16·2
	Heavy	1·7	6·0
Untreated control	Nil	24·1	28·5
	Light	12·1	12·3
	Medium	19·3	23·1
	Heavy	44·5	36·1

* This site was sprayed four times between March 10, 1960, and May 1, 1960, when the final assessment was made.

Fig. 1 shows quite clearly that there is a very marked delay in the appearance of any significant difference between the control and the treated areas in mature plantations. This experiment was carried out during the dry season, and as such the incidence of disease was not at its maximum. D. Price (late of the Cameroons Development Corporation: personal communication) has confirmed that similar delays were obtained by the low-volume application of other copper fungicides in his trials which were commenced in July 1958. One possible explanation of this delayed effect is that the copper fungicides are acting primarily as anti-sporulating agents. If this interpretation is correct, then in order to obtain a more rapid control of the disease it would possibly be necessary to have much more cover than is normally given by a single aircraft application of chemical at 1–2 gal./acre, but provided a given fungicide deposit is sufficiently persistent then repeated applications should lead to a build-up of chemical on the older leaves equal to that given by any high-volume ground application. The upper leaves of the banana plant always appear free from disease, and mature lesions only appear on lower leaves in the plant. From a microscopic examination of approximately 6,000 lesions it appears that the 'black lesions' sporulate much more uniformly than any other type of lesion, although spores are also found on the older lesions. These black lesions are most commonly recorded about half-way down the mature plant, although again they may occasionally appear on very old or young leaves. Most of these observations suggest that the main conidia-producing areas of an infected plant are middle and lower leaves, and not until these leaves are adequately covered with an anti-sporulating chemical will any marked effect of spraying from the air become apparent.

Eradicant oil applications from the air would certainly reduce the number of lesions developing to the 'black' stage, but does not prevent sporulation of any lesions that were already present[3,4], and thus a single oil application would not have any long-term effect in that the high inoculum potential present would remain. This suggests that provided climatic conditions remain conducive to the fungus, it would be necessary to apply oil to a given plant until the youngest leaf present during the first application had developed to complete maturity before the maximum effect on the incidence of disease was obtained.

Table 2 demonstrates that under the cutting-out routine, an almost immediate response to spraying was obtained, which suggests that under conditions of low inoculum potential brought about by the removal of the older infected leaves, the low-volume application of a copper fungicide also imparts some protection to the crop. This is the normally accepted explanation of the mode of action of these chemicals, but we would like to suggest that the anti-sporulation effect of such treatments as are mentioned in this report are possibly much more significant in determining field results than was previously realized. If this interpretation is correct, then the aerial application of protective and anti-sporulating fungicide could not be expected to show its maximum effects until (at least) 6–7 months after the commencement of that treatment. Furthermore, the deposits most resistant to weathering should have a marked advantage over less persistent materials.

We wish to express our thanks to the Directors of the Cameroons Development Corporation, United Fruit Co., and Fisons Pest Control, Ltd., for permission to publish these results. More particularly we would like to express our appreciation of the assistance given to us by various members of these organizations, including Drs. Forsyth, Fulton, Klein and Stover of the United Fruit Co., and Mr. Etherington and Mr. Price of the Cameroons Development Corporation.

AGE OF BED I, OLDUVAI GORGE, TANGANYIKA

By DR. L. S. B. LEAKEY
Coryndon Museum, Nairobi
AND
DR. J. F. EVERNDEN and DR. G. H. CURTIS
Department of Geology, University of California, Berkeley

OLDUVAI GORGE is justly famous because of its unique geological sequence of Pleistocene deposits, which are exceedingly rich in fossil fauna, as well as a long sequence of stages of evolution of the earlier Stone Age cultures[1].

In the monograph[1] published in 1951 the view was expressed that although Bed I differed from Bed II in faunal content, both belonged to the lower part of the Middle Pleistocene. This view was revised by one of us in 1959 as a result of reviewing the fauna collected in the series of detailed excavations during the period 1952–59 inclusive.

Leakey claimed that it was now apparent that the time-interval between Bed I and Bed II was greater than had been previously supposed, and he reverted to the view which he had published in 1935[2] that Bed I was of Lower Pleistocene age. In view of the extraordinary wealth of fossil and cultural material in the Olduvai deposits, it was not surprising when in 1959 a most important fossil hominid skull—*Zinjanthropus boisei*—was found in Bed I, at site *FLK* I, in association with faunal remains and Stone Age culture material of the Olduwan culture[3]. In 1960, thanks to the Research Committee of the National Geographic Society, the Wenner Gren Foundation and the Wilkie Trust, very extensive further work was carried out, resulting in the discovery of pre-*Zinjanthropus*[4] fossil hominid material at a lower geological level in Bed I.

Fortunately, many of the deposits at Olduvai Gorge are pure volcanic deposits, containing no derived material, and are therefore usable for the potassium–argon dating method. A preliminary examination of deposits in the Gorge and collecting of material were carried out by two of us, Leakey and Evernden, in 1958 and additional material was collected at intervals and sent to Berkeley by Leakey in 1959 and 1960. In 1961, Curtis visited Olduvai Gorge with Leakey and Richard Leakey for further collecting and study. Although many of the samples collected have not yet been studied, we all three feel that a report on those specimens which have a direct bearing on the age of the fossil hominid remains in Bed I should be published, in view of the scientific importance of these early hominids.

The three sites which have yielded hominid remains in Bed I are: (*a*) *FLK* I, the site which yielded the skull of *Zinjanthropus boisei*; (*b*) *FLKNN* I, the site which yielded the remains of a 'child', representing a pre-*Zinjanthropus* hominid; and (*c*) *MK* I, which has not been referred to in the preliminary reports but which has yielded some teeth and parts of a skull of a hominid. All three sites have yielded an archaic fauna and tools of the Olduwan culture, and are regarded as of Lower Pleistocene (Villafranchian) age.

The Bed I samples which have been dated are as follows:

KA 412 437 Basal bed in the tuff and sediment sequence of Olduvai Gorge. Sample collected immediately west of third fault on south side of gorge at knife-edge descent. This horizon can be correlated with the series

Table 1

			Top of Bed I			
KA 664	Biotite	1·39 gm.	6·96% K	1·77 × 10^{-11} mole $A_{40}{}^{r}$	93% $A_{40}{}^{at}$	1·02 × 10^{6} yr.
664*R*	Biotite	5·99	6·96	8·36	82	1·13
KA 861	Oligoclase	6·4	1·17	1·85	93	1·38
			Bottom of Bed I (hominid-containing series of tuffs)			
KA 412	Anorthoclase	29·6	3·29	28·3	67	1·63
KA 437	Anorthoclase	6·68	3·06	6·62	70	1·74
KA 846	Anorthoclase	7·91	2·52	5·55	52	1·57
KA 847	Anorthoclase	5·90	3·18	6·16	70	1·85
KA 849	Anorthoclase	6·50	2·04	4·44	77	1·89
KA 850	Anorthoclase	8·17	3·94	10·20	41	1·78
KA 851	Anorthoclase	7·79	3·69	8·37	61	1·64

of tuffs in which hominid remains have been found by Leakey.

KA 846 Site *MK*, 18 in. below hominid remains. Buff coarse-grained tuff 13 in.–14 in. thick.

KA 847 Site *MK*, just above hominid layer. Light grey tuff, 20 ft. thick. Appears to be Pelean type ash. On every criterion, this must be considered an uncontaminated volcanic deposit.

KA 849 Site *FLK* I. 11-in. crystal tuff overlying *Zinjanthropus* layer.

KA 850 Site *FLKNN* I. 2-in. ash above very fine-grained 1-in. ash resting on pre-*Zinjanthropus* floor.

KA 851 Site *FLK* I. 12-in. tuff immediately under *Zinjanthropus* floor. Sample is rather weathered and soft with numerous Zinj-time root holes.

KA 664 Sample collected near top of Bed I, some distance from the hominid sites. At time
664*R* of collection, it was thought that this horizon was older than the hominid sites and it is so described in a paper submitted for publication by the INQUA Congress, Warsaw, 1961. However, more careful field work has established unequivocally that this horizon is definitely younger than any of the hominid sites.

KA 861 19-in. soft lapilli tuff, near top of Bed I and definitely younger than any of the hominid sites.

In the area of the three hominid sites, between 25 and 30 individual tuffs and tuffaceous beds can be distinguished in Bed I. At these sites these aggregate 39 ft.–43 ft. in thickness. Most tuffs are approximately a foot in thickness, but at the *MK* site the tuff immediately overlying the hominid floor is 129 in. In order of abundance, the tuffs fall into the following categories: anorthoclase-bearing vitric-crystal tuffs; anorthoclase-bearing crystal vitric tuffs; oligoclase bearing lapilli tuffs; and tuffaceous sandstones.

Within individual beds faint lines of stratification and evidence of size sorting may sometimes be seen. Some beds, however, show little or no sorting, vary tremendously in grain and lapilli size and exhibit characteristics of nuée ardente deposits. This is true of the tuff overlying the hominid remains at *MK* site. Some of the crystal vitric tuffs show marked crossbedding and have probably been re-worked. Most beds, however, appear to be primary ash falls.

Vitric shards in most of the tuffs have been more or less altered to clay, but the crystals appear fresh. Dark and strongly altered tops of some tuffs probably marked old soil zones. Numerous root casts below such zones strengthen this interpretation. Angular quartz and quartzite fragments are obvious in only a few of the tuffs. The nearest source of basement complex contaminants of this type is an inselberg of quartzite and gneiss approximately 1½ miles north of the hominid sites. More common visible contaminants are bone fragments. These are usually confined to thin strongly weathered layers; but in some cases, as in the tuff below *Zinjanthropus*, occur throughout the tuff.

Reck believed that the source of these tuffs was to the east, and the rapid thickening and coarsening of the strata in that direction is convincing proof that this is so.

At the *FLK* and *FLKNN* sites the hominid remains occur approximately 15 ft.–16 ft. above the basalt flow at the base of Bed I, while at the *MK* site, the hominid remains occur 9 ft. above the basalt. The samples dated, with the exception of *KA* 851 below the *Zinjanthropus boisei* floor which contained numerous bone fragments, showed no visible contaminants. In four of the six samples, the glass shards had been almost completely altered to clay. In one of these, *KA* 849, about 20 per cent of the glass shards were fresh, while in *KA* 847, from just above the hominid remains at *MK* site, most of the glass shards were fresh. Whether the more intense alteration of the four samples is the cause of their somewhat younger ages is not known, but it appears reasonable.

The run data and derived ages are given in Table 1.

The decay constants used in the computation of ages are $\lambda_{\beta} = 4{\cdot}72 \times 10^{-10}$ yr.$^{-1}$, $\lambda_{k} = 0{\cdot}584 \times 10^{-10}$ yr.$^{-1}$. The standard deviation of all of these runs is 0·1 × 10 yr. or less. This figure is, of course, simply a measure of the reproducibility of our results and does not attempt to deal with geological factors which might cause some scattering of the derived ages.

These samples were critically selected and examined and there seems to be no chance of their being contaminated by older eroded debris. It is to be noted that the hominid-site dates fail to fall in the proper relative order but all are between 1·6 and 1·9 million years. At the present time, the best estimate that we can make of the age of these sites is the average of the several ages, that is, 1·75 million years. This figure is in excellent agreement with *KA* 412, which is at the same stratigraphic level, but which was sampled a few miles from the hominid sites. The two samples from the top of Bed I give an average age of 1·23 million years, that is, 0·5 million years younger than the hominid sites. It may be of interest to note that we have obtained[5] an age of 360,000 years on a post-Chellean II tuff in Bed II, Olduvai. The conclusion is inescapable that Olduwan culture and Villafranchian fauna are synchronous in time and that both are approximately 1·75 million years old.

Interpretation of Cosmic Noise Measurements at 3·8 Mc./s. from Satellite 1960 η1

THE results of measurements of cosmic noise at 3·8 Mc./s. from the satellite 1960 η1 have been reported by Molozzi, Franklin and Tyas[1]. A puzzling feature was the variation in field-strength at different locations. These results have now been analysed, on the assumptions that variations in signal strength are due to three causes: (*a*) the variation of radiation resistance of the antenna due to the ionosphere surrounding of the satellite; (*b*) the restriction in angular aperture of the satellite antennæ due to the ionosphere; and (*c*) the variation of cosmic noise power over the sky. The results indicate that these are the most important factors affecting the cosmic radio signals.

The variation of cosmic noise across the sky can be removed from the field-strength data by plotting noise-field contours along the orbit, using one of the sky maps such as that computed by Steiger and Warwick at 18 Mc./s. (ref. 2). The field-strengths can then be normalized to a standard value of the cosmic-noise field. In this communication the field-strength is normalized with respect to a region of the sky remote from the centre of the Galaxy, where the variation was small and the sky temperature low. Variation in antenna gain over the region is neglected.

The remaining variation in cosmic-noise levels is predominantly due to the effect of the ionosphere, neglecting for the moment the effect of the restriction in angular aperture. It can be shown that the radiation resistance of loop antennæ, such as those used in the experiment, varies as $\varepsilon^{3/2}$, ε being the dielectric constant of the medium. Therefore, as the antenna is immersed in ionosphere of increasing electron density, the resistance due to radiation will decrease, and hence the cosmic-noise power output from the receiver will also decrease.

The largest values of the electric field-strength are assumed to be representative of the noise field outside of the ionosphere, where the dielectric constant is unity. It follows that the ratio of the noise field-strength measured in the ionosphere to that outside the ionosphere, is proportional to $\varepsilon^{3/4}$, when absorption in the upper F region of the ionosphere is assumed to be negligible.

Since several modes, particularly the ordinary and extraordinary modes, can be propagated independently in the ionosphere, each one can contribute to the total noise-power at the satellite. The assumption was made that the energy was evenly divided between the two components above the ionosphere, that their signals added incoherently at the satellite and that the gyro-frequency was of the order of 1·4 Mc./s. at an altitude of 800 km.

Based on the hypotheses in the preceding two paragraphs, first estimates of the values of the dielectric constant and the electron density at the satellite were computed for each of the 22 observations reported by Molozzi *et al.* Since the largest values of the field-strength were observed over Woomera, these values were taken to represent the field-strength outside the ionosphere.

In order to arrive at more precise values of ε, it is necessary to allow for the angular aperture θ of the antenna, by a method of successive approximations. In the limiting case, $\sin\theta = \sqrt{\varepsilon}$.

Using the first value of ε calculated above, the angular aperture can be determined, and a more precise value computed for the noise-field received at the satellite, averaged over the region of the sky being viewed. Following the same procedure as before, a second approximation of the dielectric constant can be arrived at. The procedure can then be repeated and mean values of the electron density found by this means for the North American telemetry stations, Ottawa, Blossom Point and Fort Myers.

Date	Local time (approx.)	Mean height of satellite	Electron density
June 24–26, 1960	2200 hr.	870 km.	$9{\cdot}2 \times 10^4$ per c.c.
June 27, 1960	2200 hr.	855 km.	$10{\cdot}4 \times 10^4$ per c.c.
June 24–26, 1960	1400 hr.	1,050 km.	$7{\cdot}5 \times 10^4$ per c.c.

The difference in electron density between the measurements on June 24–26 and June 27, at the same local time, is approximately 10 per cent. Since a magnetic storm began with a sudden commencement at 0146 G.M.T. on June 27, it is surmised that the increase is due to the effects of the magnetic storm. The observations on June 27 were all made within 6 hr. of the beginning of the storm, during the initial positive phase of the variation of magnetic field.

The sky brightness temperature T computed from the results obtained over Woomera was found to be $8{\cdot}1 \times 10^6$ °K. in the vicinity of R.A. 5·5 hr., Dec. $-30°$, the region used for normalization of the values of field-strength.

A more detailed report will be given elsewhere.

ASTROPHYSICS

Apparent Recession of Nebulæ and the Nature of Radio Stars

IN a recent communication[1m], a brief summary was given of the quantitative evidence in favour of the whirl theory of light and matter, according to which the whole physical universe is the manifestation of Maxwell's electromagnetic waves, wherein the fundamental particles of matter are represented as integral solutions of Maxwell's equations *in vacuo*, in cylindrical co-ordinates, extended from a low limit of the variable parameter of the integrant solution to infinity (the 'compound whirl'), while the photons are represented by the same kind of solution but with a finite upper limit (the 'fragment'). The system of electromagnetic waves represented by the integrant solution was called the 'simple whirl'[1b,1j]. The energy of a fully realized compound whirl is finite, notwithstanding its infinite extension in space, and therefore the fundamental particles of matter are stable[1b,1j]. On the other hand, the total energy of a fully realized fragment would be infinite and therefore it can only be partially realized at the emission and then spread transversally asymptotically tending to its full realization and, at the same time, it must move in the axial direction asymptotically (though with great rapidity) tending to the theoretical 'velocity of light'[1j]. Thus the photon can be regarded as a fragment of a fundamental particle of matter. Its emission, however, does not affect the stability of the emitting fundamental particle, because the upper limit of the integral solution that represents it remains infinite after the emission and only the lower limit becomes slightly higher; its total energy remains finite. The quantum relationship at the emission is determined by Maxwell's electrodynamics[1j,f-l,a].

The spreading of the photon also implies a continuous increase of the wave-length λ, which very rapidly, though asymptotically, tends to proportionality to the distance from the source of emission according to the equation:

$$\frac{\Delta\lambda}{ct} = \frac{\sqrt{2\pi^3\chi_1}}{(q_0\ r_0)^4} \tag{1}$$

(derived by simple transformation from formula (7·9), ref. 1*j*), where t is the time elapsed since the emission of the photon, c is the velocity of light, $\chi_1 = 0{\cdot}0575$ (*ibid.*, formula 8·5) is the average value of the above-mentioned dimensionless lower limit of integration of the integral solution representing the electron or the proton; $q_0 = mc/\hbar$ (where m is the mass of the emitting particle, $\hbar \equiv h/2\pi$ is the Planck constant); r_0 is the radius of the photon at the moment of emission.

This formula permits the determination of r_0 from the generally accepted results of observation. According to the data given by Sir Arthur Eddington[2]:

$$\frac{\Delta\lambda}{{}^0\lambda} = 5{\cdot}75 \times 10^{-24}ct \tag{2}$$

where ${}^0\lambda$ is the wave-length of the photon at the emission.

It can be found from (1) and (2), on substituting the constants, that, for example, for ${}^0\lambda = 4 \times 10^{-5}$ cm. (violet light) $r_0 = 7{\cdot}6 \times 10^{-5}$ cm., whence $2\pi r_0/{}^0\lambda = 3{\cdot}8\pi$. From this it can be found (formula 9·8, ref. 1*b*) that the prevailing part (more than 93 per cent) of the energy of the emitting electron is contained within this radius and hence that the pattern of the emitting particle and of the emitted photon should not be substantially distorted at the emission.

Thus the shifting toward the red of the spectral lines of nebulæ, proportional to their distance from the point of observation, does not require for its explanation the hypothesis of the 'expanding universe' and hence it can scarcely justify the cosmic speculations generated from this hypothesis.

This is equally true in relation to similar phenomena in the radio stars. From the point of view of the whirl theory the radio stars should be regarded, at least for the time being, in the absence of more direct information about their nature, as consisting of atom and molecule-like formations of particle-like compound whirls of comparatively large dimensions ('macroparticles'), which should emit photons of correspondingly large dimensions ('macrophotons'). To evaluate the order of magnitude of macroparticles, we may assume that the scale relationship between the macrophotons and the emitting macroparticles is of the same order as between the photons and the emitting electrons. Taking again the violet light as an example, this ratio $h/(mc\,{}^0\lambda)$ is about 6×10^{-6}. The average order of wave-length of radio-astronomical signals, which we can regard as macrophotons, is about 10 cm. and hence the wave-length h/mc of macroparticles should be of the order of 5×10^{-4} cm. Thus, assuming that the Planck constant of the macroparticles is the same as of the fundamental particles of matter and of the photons, the mass of the macro-electron must be of the order of $3{\cdot}6 \times 10^{-33}$ gm. and that of the macroproton of the order of $6{\cdot}65 \times 10^{-30}$ gm.

It seems likely that macroparticles can, at least occasionally, be formed from the vortices (that is, revolving clouds) of particles of matter. As was pointed out on a number of occasions[1b,j,m], de Broglie undulations are implied in the solutions of Maxwell's equations representing the whirls. In an assembly of whirls (and hence also in an assembly of particles) they tend to become distributed in such a way that the pattern of de Broglie undulations by themselves should satisfy, or at least be near to, a solution of Maxwell's equations, superimposed upon the set of solutions representing the constituent whirls, so that the latter should form a fine structure of the former. No rigorous proof of this proposition was attempted, but it was applied tentatively to gravitation[1j,k,m], and it led to the correct determination of the period of rotation, and of the sidereal motion, and of the distance from the Sun, of Mercury, and of the period of rotation of Venus[1j,k,m].

It seems, therefore, likely that a system of de Broglie waves of protons and electrons revolving together in a vortex can occasionally emit a macroparticle the mass of which is very small in comparison with the mass of the vortex itself. The following consideration should increase the plausibility of this approach. The revolving particles in a vortex generally tend to acquire equal moments of momentum in relation to its axis. Hence their linear velocities tend to become inversely proportional, and the de Broglie wave-lengths tend to become proportional, to the distance from the axis, or, in other words, the angular wave-length of de Broglie waves tends to become constant. This answers the general description of electromagnetic whirl.

The macroparticles can form the atoms and molecules in the same way as the electrons and protons, and where their mass ratio equals the mass ratio between the proton and electron, they will form macroatoms and macromolecules geometrically similar to the atoms and molecules of matter.

GEOPHYSICS

The Frequency of Meteorite Falls throughout the Ages

IN a recent article[1] Prof. H. Pettersson describes his investigations of samples of deep-sea deposits in which were found metallic spherules, mostly less than 250μ in diameter, to which it is reasonable to ascribe a meteoric origin. These occurred in several geographical regions and in layers of various geological ages, and among the conclusions reached is the following: "In general, the number of spherules is greatest in the more recent sediments. Nevertheless, substantial numbers of spherules were found in layers of Tertiary age: this contradicts the assertion made by some authorities that no meteors fell on the Earth during that time". A reference identifies the "authorities" mentioned as the late Prof. F. A. Paneth, who, in a paper in *Vistas in Astronomy*[2], wrote: "The result of our discussion is that *glass meteorites fell on our Earth only during the late Tertiary and early Quaternary; that iron and stone meteorites did not fall before the late Quaternary; that centuries ago the fall of iron meteorites was a much more common phenomenon than to-day; and that even since 1800 meteorite falls seem to have become noticeably rarer*".

It is clear from Paneth's paper that he is discussing meteorites only, and the evidence which he gives for his statement can refer only to those bodies. He consistently emphasized the lack of evidence that meteors and meteorites have a common origin[3], and there is nothing in his conclusions that is inconsistent with Pettersson's findings. Pettersson uses the counts from his samples to generalize for the whole Earth, and concludes that the present rate of accretion is 1,000–5,000 tons per annum. Such a generalization from any sample of meteorite falls would clearly be quite invalid. It follows that Paneth's conclusions regarding the fall of meteorites in past times are unaffected by Pettersson's important observations.

In view of the recent revived interest in the analysis of meteorites[4], it might be timely to point out that Paneth's considerable collection of meteorites is now, by his wish, available for experimental study. The secretary of the "Paneth Meteorite Trust", who would welcome applications from qualified investigators, is Dr. H. Wänke, Max-Planck-Institut für Chemie, Mainz, Germany.

[4] See, for example, Bernal, J. D., *Nature*, **190**, 129 (1961).

Murray's and Renard's interpretation of the "cosmic spherules" found in deep-sea deposits[1] that they are of cosmic origin, and were probably derived from iron meteors heated to superficial melting during flight through the atmosphere, seems to be generally accepted at present. Having myself studied hundreds of such spherules, extracted from deep-sea cores taken by the Swedish *Albatross* Expedition (1947–48), I have found Murray's description of their external structure confirmed. In addition, analyses of the composition of individual spherules by the Castaign microanalyser[2] has confirmed that they contain, besides iron, also nickel and cobalt, which supports their extra-terrestrial origin as well as Murray's hypothesis that they are derived from meteors of the nickel-iron type.

The resemblance between their surfaces and that of the iron meteorites seems to support the view that they may be derived from meteorites as well as from meteors which have not reached the surface of the Earth. The presence of cosmic spherules in deposits of Tertiary age (recently confirmed by Germans investigating the "Buntsandstein" in north-west Germany) certainly supports the view that they indicate meteoric activity long before the Quaternary.

Whether the origin of meteorites and ordinary meteors is different seems to be an open question. Whipple assumes most meteors to be of cometary origin, whereas meteorites are usually assumed to be derived from planetary fragments like the asteroids. It seems to me that the origin of the meteorites and, still more, of the tektites is still under debate, whereas the origin of the cosmic spherules is that announced by Murray.

My calculation that the accretion of cosmic spherules to the Earth is 1,000–5,000 tons annually is, of course, due to extrapolation from the counts made by myself and my co-workers in a limited number of cores. I hope to obtain a more dependable figure from the much longer cores to be raised by the Moho-Project.

RADIOPHYSICS

Scintillations and the Latitude Distribution of Ionospheric Irregularities

KENT[1] has reported a series of observations on the 40 Mc./s. transmissions from *Sputnik* 1 made at Cambridge during October 1957. He found that the transmissions always underwent rapid fading (scintillation) when the satellite was north of Cambridge but only occasionally when south of Cambridge. He concluded that the scintillations were due to ionospheric irregularities which are north of the observing station but not south of it. Further, since the southward extent of the scintillation region was greater for satellite passes to the west of Cambridge than to the east, he postulated that the density of the irregularities is controlled by the magnetic rather than geographic latitude (Cambridge's declination is about −9°). Mawdsley[2] objected to Kent's seemingly arbitrary assumption that the irregularities do not occur south of the observer, on the grounds that radio star scintillations are observed at lower latitudes than that of Cambridge. He suggested an alternative interpretation of Kent's results in terms of preferential forward scattering by the irregularities, assumed to be field aligned, when the line of sight from the observer to the source is normal to the field lines. Afterwards, Bain[3] and Frihagen and Tröim[4], working at Slough and Kjeller respectively, observed scintillations when the satellite under observation was south of the observing station. However, they both found that the scintillation activity increased for geomagnetic latitudes greater than that of Cambridge, that is, 55°. This led Frihagen and Tröin to support Kent's interpretation. It is the purpose of this communication to point out the existence of further pieces of evidence which support Kent's point of view rather than Mawdsley's.

It has long been known that the scintillation of radio stars correlates strongly with the occurrence of spread-F (for example, Booker[5]), and recent work[6,7] has shown this correlation applies to scintillation of satellite signals also. The distribution of scintillation activity with latitude may therefore be expected to be similar to that of spread-F. Singleton[8] has shown that the distribution of spread-F depends on geomagnetic latitude and, further, that between 60° and 70° the percentage occurrence rises from about 10–80 per cent or more. Simple calculation shows that the north–south tangent to the Earth's surface at an observing point cuts the 300-km. level at points the latitudes of which differ from that of the observing point by ±17°. For Cambridge (geom. lat. 55°) the range of geomagnetic latitudes over which the 300-km. level is observable is thus 38° N.–72° N. For the 400-km. level this range is 35° N.–75° N. It is clear, therefore, that if the irregularities responsible for the spread-F and scintillations are in the 300–400 km. region, as is believed to be the case, the observed marked increase in scintillation activity when the satellite is north of Cambridge is to be expected. This explanation does not preclude the possibility of observing scintillations at geomagnetic latitudes south of 55° since the incidence of spread-F nowhere falls to zero, and indeed, since spread-F activity increases again at the geomagnetic equator, an increase in scintillation activity would be expected here. This is observed[9].

The departure of the zenith angle dependence of the annual mean radio star scintillation index from the simple secant law, as pointed out by Hewish[10] in Cambridge and Little and Maxwell[11] in Manchester, can possibly be explained in a similar way. This secant law, which takes into account the variation of layer thickness with changing zenith angle, tacitly assumes a constant distribution of irregularities over the region of observation. The Cambridge and Manchester data are obtained mainly from observation of Cygnus and Cassiopeia, the lower culmination of each of which is near the northern horizon of these stations. Thus the larger the zenith angle, the further will the point of intersection of the radiation with the F_2 layer penetrate into the region of incidence of high irregularity to the north, and the larger will be the departure from the secant law. It can be shown that the latitude of the point which is at a height of 300 km. on a ray making a zenith angle of 60° at the observer in the meridian plane differs from the latitude of the observer by 4°. Since Cambridge and Manchester have geomagnetic latitudes of about 55° and 56° respectively and the increase in irregularity activity commences at geomagnetic latitude 60°, the departure from the secant law would be expected to commence at zenith angles of about 60°, as is observed.

An increase in scintillation activity with zenith angle has also been observed at middle latitudes[12], where the latitude distribution of irregularities is flat. However, the crude method of analysis used in this case makes it impossible to draw any conclusion as to whether the secant law can explain the variation or not.

Mawdsley's contention that the most favourable condition for forward scattering by field-aligned irregularities is when the incident radiation is normal to the field lines is contrary to experiment. Singleton, Lynch and Thomas[13], working with a field of view (geom. lat. 15° S.–55° S.) over which the incidence of spread-F is substantially flat, have shown that an enhancement in scintillation activity is experienced for propagation along the field lines, there being no enhancement for propagation normal to the field lines.

It would appear, therefore, that Kent's original interpretation of his results is in accord with the spread-F findings and that the scattering mechanism envisaged in Mawdsley's alternative explanation is not borne out by experiment. As a result it is asserted that Kent's explanations must be accepted.

PHYSICS

Pulse-shortening in Electron Linear Accelerators

Kelliher and Beadle[1] have published some preliminary observations of the phenomenon of pulse shortening in electron linear accelerators.

Since the problem was first noted[2] investigations have also been in progress in our laboratories. It would now appear that a satisfactory theory has been evolved and experimentally verified as a result of which various methods of avoiding the problem can be devised. Kelliher and Beadle suggested that the effect could be due either to spurious radio-frequency modes or to a 'field effect' associated with power level. It has in the past been difficult to see how a spurious mode could attain sufficient power-level to produce the very large forces required to affect a high-energy beam.

This difficulty has now been resolved by the realization of a significant difference between the action of forward and backward waves. The expression for the tranverse forces associated with a forward travelling-wave acting on a beam contains a term of the form $(1/\beta - \dot{z}/c)$, where β is the ratio of the phase velocity to light velocity, and $\dot{z}$ and c represent beam and light velocity respectively. For a forward wave this term approaches zero as β and $\dot{z}/c$ approach unity, indicating a balance of transverse electric and magnetic forces.

Considering a backward wave, however, it can be seen that in order that energy be transmitted in a direction opposed to the phase velocity the sign of the Poynting vector must be reversed, that is, the H vector must show a phase reversal in its relationship to the E vector as compared with the situation in a forward wave. From this, it follows that the sign in the expression given above will be changed and the electric and magnetic terms will now add and thus any disruptive forces will, in a backward wave, be very much higher than in an otherwise similar forward mode. Consideration of the higher modes which exist in a corrugated wave-guide structure does reveal the existence of backward waves. It can thus easily be seen that there is, in the normal form of linear accelerator containing long uniform sections of corrugated wave-guide, the possibility of action as a backward wave oscillator and, even if only modest power be produced, transverse forces could be large.

An experimental investigation of possible modes in a corrugated wave-guide structure having $a/\lambda = 0 \cdot 11$ and for which the normal E_{01} mode has $\beta = 1$ at 2,998 Mc./s. has been carried out by I. White of this laboratory. The measurements show that there is (among others) an E_{11} mode which is a backward wave and that this wave has a phase velocity equal to light velocity at 4,436 Mc./s., under which conditions its group velocity is 0·038 c. Perturbation measurements of the series impedance (E^2/P) confirm that mode powers of the order of kW. would cause transverse forces sufficient to deflect a high-energy beam. One might therefore expect that a uniform accelerator section of 1½ m. length of this guide fed by a bunched beam travelling at near light velocity would oscillate at a frequency of 4,432–4,433 Mc./s., the slight shift in frequency being necessary to allow for the phase-change between beam and wave from end to end of the section. A bunched beam of energy 8 MeV. and indeed 16 MeV. has been injected into such a section of accelerator and pulse-shortening effects were exhibited both when energized at a power-level of 5 MW. from an S-band klystron and when completely unenergized. Measurements were made at the input end of this section and power was detected at a frequency of 4,433 Mc./s. Examination of the variation of this power with time indicated a rapid increase at the end of the shortened electron pulse. When beam current was reduced until pulse-shortening no longer took place, no power at 4,433 Mc./s. could be detected. There seems no doubt, therefore, that pulse-shortening in this case was associated with backward wave oscillation in the E_{11} mode. Means were taken as mentioned below to reduce the possibility of E_{11} wave build-up and no pulse-shortening could then be detected.

These findings confirm the suggestion that the E_{11} mode is responsible made in the paper by Nygard and Post[3], although they did refer to an E_{110} mode of oscillation. The significance of the 0 is a little obscure as this would with normal cavity nomenclature imply a phase velocity of infinity, that is, that the wave was operating at cut-off. With the type of oscillation we are considering it is, of course, not necessary that the guide should act as a resonant cavity. The E_{11} mode near $\beta = 1$ is such that to a first approximation the fields in the axial region may be regarded as those of a plane wave with, of course, the significant difference that the E and H vectors are phased so as to give the backward group velocity, and the oscillatory motion of the beam will, therefore, be purely transverse. For this reason the longitudinal bunching of the beam at the E_{01} frequency has little or no influence on the build-up of oscillation. The theory has been carried to the extent of fitting known facts qualitatively and rough quantitative agreement has also been obtained. It is hoped that a complete theory will be published in the near future.

Having determined the causes of trouble it is relatively simple to devise means for avoiding them. On the above theory it is quite clear that the constant field guide suggested by Kelliher and Beadle with its essential non-uniformity would avoid the difficulty of pulse shortening. Similarly, arrangements using combinations of shorter uniform sections of different a/λ as used in some of our own accelerators would again avoid the difficulty. More elegant methods of avoidance are possible; for example, new accelerating structures may be used which are incapable of propagating the mode at velocities near that of light, such as that mentioned by Nygard and Post (possibly having $2\pi/3$ phase change per corrugation). Techniques using short sections which cause phase shift between the E_{11} mode and the beam have been used in our own laboratories. It is perhaps worth noting, however, that there are other higher modes which may cause similar troubles although it seems probable that higher starting currents for the oscillation would be required. Although, at present, difficulties seem to have been removed, similar troubles may occur due to these higher modes if and when beam currents are pushed an order of magnitude higher. In this connexion, it is perhaps significant that in the experiment with the accelerator section, mentioned above, a small amount of power has been found to exist under pulse-shortening conditions, at other frequencies, particularly at approximately 7,970 Mc./s. This mode has not yet definitely been identified, but may possibly be the E_{31}. Although it has been reported that pulse-shortening has not been observed on L-band accelerators, it is quite clear that such high mode problems could exist and it is probable that they would be found if the beam current were increased sufficiently.

As regards performance of S-band accelerators, we have in our laboratories a single-section accelerator operating from a 5-MW. klystron and have achieved beam current in excess of 1 amp. at 2 μsec. pulse-length and at an energy of 4 MeV., that is, almost complete radio frequency power absorption without any signs of pulse-shortening.

Displacement Potentials and Bending of Rod-like Polyelectrolytes

In 1954, Jensen *et al.*[1,2] discovered an electromechanical property of solutions of potassium hyaluronate. They named the effect 'flow-potential', but agreed later on to change the name into 'displacement-potential'. The original measurements were performed with techniques including amplification. Experiments in 1959 by us[3] (C. E. Jensen died in November 1959) showed that the classical potentiometric technique without amplification was quite sufficient to measure the potentials. The new measurements corroborated the original findings. Beyond this Jensen and Vilstrup discovered that the potentials were independent of the distance between the electrodes[4].

It seems that the observed phenomena can be derived from the properties of a crude model of the hyaluronate molecule: the molecule may be described as a long cylinder near the core of which a great number, for example 1,000, of negative elementary charges are distributed evenly. The core is surrounded by a sheath of positive electricity evenly distributed on a cylindrical surface. This assumption is based on the fact that the potassium ions are prevented by elastic and electric forces from moving in directions perpendicular to the surface while they are (nearly) free to move in the other two directions. We now inquire what will happen if we bend the cylinder. From the geometry of the toroid, it is known that a cylinder can be bent without any change in surface. What happens is that part of the surface is moved from the inside to the outside. Since the radii of curvature in question are large compared with the diameter of the cylinder, we must assume that the bending cannot cause significant changes in the even distribution on the surface. Therefore, the electrical effect of the bending will be the following: (*a*) if a number of molecules are bent simultaneously the same way, a certain, not negligibly small, amount of electricity will be displaced from the inside to the outside of the molecules under bending; (*b*) when the bending has ceased and the bending stress has disappeared, the bent molecules will tend to unbend, that is, they will tend to chase electricity in the opposite direction, against their centres of curvature. In other words, the entire solution, after bending, is in a state of strain which manifests itself as an electromotive force, tending to chase electricity in the direction from the molecules to their centres of curvature.

A typical experiment is performed as follows: a glass capillary is partly filled with a dilute solution of potassium hyaluronate, for example, with a 1 per cent solution. Two electrodes enter the solution from the sides of the tube. The discoverers of the effect observed two phenomena: when the solution is displaced from left to right relatively to the capillary, the measuring instrument shows that the right electrode is negative during the displacement and when the displacement has ceased its sign is reversed. Thus, the right electrode becomes positive and remains so, as long as the solution remains in the displaced position, or rather, the potential decays slowly, by some 10 per cent in the course of a day.

It is evident that, on account of the shearing forces existing in the solution during its displacement in the capillary, the long molecules must be bent so that most of them will have their insides pointing in the direction of the movement of the liquid. It will, therefore, be seen that predictions based on the model described here are in complete qualitative agreement with the observations. This agreement is corroborated by a third observation: when the capillary is emptied after an experiment and refilled with water without rinsing it, a displacement potential about ten times as large as before is observed[3]. In these circumstances, most of the molecules adhere to the glass and their bendings will be more acute, which must result in an increase of potential. Filling the capillary (internal diameter about 0·7 mm.) with thin glass rods has a similar effect[5].

The order of magnitude of the potentials is 5–10 mV. for experiments of the ordinary type, and for those of the kind described about 100 mV. Preliminary estimates based on the model in question yield results agreeing with these values. It follows from the estimate that the potential must be inversely proportional to the length of radius of curvature.

More detailed papers on the theory of the effect and its applications to the mechanism of hearing will be published elsewhere.

Electrical Effects observed in Polycrystalline Boron

THE conductivity of vacuum-fused polycrystalline specimens of boron is observed to increase in a magnetic field instead of decreasing as expected theoretically. Different samples exhibit the effect to different extents, but all show saturation at a field-strength of about 3,000 gauss. Increases of up to 1 part in 10^3 at saturation have been observed.

Preliminary measurements indicate that the effect persists at low temperatures but decreases above room temperature, falling below the noise-level at about 100° C. in the most sensitive specimen.

The effect shows no temperature hysteresis and is unaffected by changing the ambient atmosphere from air to argon. It is independent of the orientation of the magnetic field relative to the current vector.

All specimens examined were *p*-type by thermoelectric measurement, and contained a variety of traps as evidenced by the long time-constants observed in other measurements. The 'magnetoconductance' effect itself, however, could be measured at frequencies up to 10 kc./s., the limit set by the measuring system used. No reliable zero-frequency measurements have been made owing to the difficulty of maintaining the boron temperature constant to 0·01° C., rendered necessary by the strong dependence of conductivity on temperature.

Samples of polycrystalline boron also exhibit a 'charge storage' effect. To show this, current is passed through a piece of boron for a few seconds and then the source of current is replaced with a current meter. A charge passes through the meter in the same direction as would result from charging and discharging a capacitor in the same way.

Typically, a 100-V. battery is used to charge a 2-mm. thick slice cut from a 6-mm. diameter rod of boron and 10^{-8} coulomb flows through the meter. The discharge curve can be resolved approximately into two decreasing exponentials, with time-constants of 6 sec. and 180 sec.

In a further experiment, the boron is lowered into liquid nitrogen with the battery still connected, thereby 'freezing in' the charge. On substituting the meter for the battery and allowing the boron to warm up, charge is released at certain temperatures which are presumably related to the depths of specific kinds of traps in the boron. The experiment is thus analogous to the production of a 'glow curve' in the examination of a luminescent material.

Some of the boron used in these investigations was prepared in this laboratory by an electron beam zone melting process and the remainder purchased as zone-refined material prepared by the Eagle-Picher Research Laboratories, Miami, Oklahoma.

Electrical connexion to the boron was through baked-on silver paste contacts which were substantially ohmic.

The observations described differ from, but may be related to, the 'magnetic pulse' and 'colour memory' effects studied at the U.S. Army Signal Research and Development Laboratory, Fort Monmouth, New Jersey[1].

GEOLOGY

Age of the Orogeny and Granites in South-West England

Mr. Butcher's valuable contribution[1] to this puzzling problem raises a number of points which I would like to answer.

First, there is no evidence that the deformation of the pre-Permian rocks of south-west England was delayed until Stephanian or post-Stephanian times. On the other hand, there is some evidence[2] that metamorphosed, schalstein and spilite areas (and perhaps even the Delabole Slates) were being eroded somewhere south of Wales in Pennant Series (that is, Morganian) times. Hints of early Morganian instability occur in the Bristol Coalfield and in the south-eastern portion of the South Wales Coalfield. Dr. Kelling has recently been studying Pennant rocks in South Wales and is finding that over considerable southern and central areas of that coalfield a mainly southerly source (not too far away either) and a parent mass of rocks like those of Devon and Cornwall are indicated.

Secondly, similarity of fold system[3] does not necessarily prove contemporaneity of deformation. The folded and thrust south-west England sediments (the age of which has not been proved beyond about the Modiolaris Zone) are separated from the Somerset area by the powerful Cannington Park thrust-belt (which could have brought into juxtaposition rocks deformed at different times of the Carboniferous).

Thirdly, no one has ever suggested that the granites were being eroded during Pennant Sandstone (or even later Carboniferous) times. I agree with Mr. Butcher that these granites, when intruded, would be deeply buried. I also agree that "at the present level of erosion, the youngest sediments so far recognized by fossils are referable to the Upper Gastrioceras Zone[1]". There could still, however, have been an appreciable thickness of later Ammanian (for example, Similis-Pulchra Zone) deposits above this "present level of erosion" when the granites were intruded. In other coalfields of England and Wales, the thickness of the Ammanian succession above the Amman Marine Band is at least equal to (and in some cases almost double) that of the underlying Coal Measures. This thickness in the Somerset Coalfield (the one nearest Devon) is about 2,000 ft. If the south-west England area was experiencing a renewal of thick greywacke-type deposition in later Ammanian times, then that higher succession could have attained a thickness of many thousands of feet. Prentice (ref. 4, p. 408) has suggested that quite thick greywackes could have been deposited in a relatively short space of time. The granites could then have been intruded during early Morganian times and yet be buried under a considerable thickness of earlier Coal Measure rocks.

I would (with caution) suggest another possibility to account for the depth of burial in Morganian times of the granites. Great thrusts occur in the Armorican fold belt of Cornwall and south Devon. Such thrusts may have carried masses of Devonian, or older, rocks (removed by later erosion) well north over areas of deformed Culm. There could then have been thrust-masses of pre-Carboniferous rocks on top of the Culm, (*a*) when the granites were being intruded and (*b*) when the Pennant Series was being deposited farther north. Such an interpretation might even explain the presence of Devonian limestone pebbles (of southern aspect) in the New Red Sandstone near North Tawton, Devonshire[5]. The high percentage of Devonian fragments in the Permo-Triassic breccias of south-west England[6] might also be explained in this way.

Lastly, while derived Dartmoor granite is unknown in these breccias, a considerable percentage includes porphyries which could have been connected with the granite intrusions[6].

I therefore maintain that the case for a very late Carboniferous orogeny in south-west England, and also for a Permian granitic injection, has not been proved. On the contrary, available evidence supports an earlier (probably early Morganian) age for the main deformation of the Devonian and Culm rocks of Devon and Cornwall. The granite intrusions probably accompanied this deformation.

[6] Wells, A. K., and Kirkaldy, J. F., *Outline of Historical Geology* (London, 1958).

I feel that the evidence cited by Mr. T. R. Owen does not necessarily support an Upper Westphalian (Morganian) age for the orogeny and granites. An intra-Westphalian orogeny could only be satisfactorily demonstrated by the discovery of younger unconformable Carboniferous sediments, as, for example, in northern Spain[1]. Such post-orogenic sediments are not known in Devon and Cornwall. However, our knowledge of this region is still very meagre, and it may be that they will yet be found. Meanwhile, it seems to me preferable on the present evidence to correlate the main orogeny in Devon and Cornwall with that in adjacent regions to the north. In this, I agree with Kulp *et al.*[2] and Lambert and Mills[3]; but also with Mr. Owen that the case has not been proved.

I imagine that a major orogeny ending with a granite batholith and associated mineralization, such as we now see exposed for more than 100 miles in south-west England, would require a considerable time (perhaps 20 million years) for its development. The whole of the Carboniferous period is thought to be 65 (ref. 4) or 80 (ref. 5) million years. Therefore, with pre-orogenic sedimentation known to be still going on in Lower Westphalian times, I suspect that the granites (and there is more than one time of granite intrusion) could not have been emplaced in the Upper Westphalian. It is of interest that the most recent age determinations of the Dartmoor granites[6] give a slightly *younger* age compared with previous values. The new date of 265 ± 5 million years falls nicely within the Permian period on Kulp's time-scale[4].

CHEMISTRY

Evaporated Carbon Films of Large Area for Adsorption Studies by Electron Bombardment

The use of evaporated carbon films for adsorption studies is desirable in view of the difficulty of outgassing carbon powder. By analogy with the comparative properties of metal surfaces produced by evaporation and by reduction of powders, it seems likely that evaporated carbon should be significantly cleaner and more reproducible.

Following common practice with metal films, Sykes and Thomas[1] used a carbon filament mounted on tungsten leads with 'Aquadag'. The extent of evaporation was limited to a few per cent of the total carbon by electrical failure due to 'hot spots'. As a result the film thicknesses were generally of the order of 500 Å., corresponding to weights of the order of 2 mgm. Krypton adsorption isotherms showed that the residual filament had an area several times greater than that of the film, hence it was necessary to remove the remaining filament through a constriction and to seal off. This is inconvenient, and an undesirable feature if cleanliness is to be maintained.

The new technique avoids this difficulty by allowing almost 100 per cent evaporation of the carbon used. A second improvement is that only a light electrical contact to the carbon is required so that difficulties of mounting the carbon are reduced, 'Aquadag' can be dispensed with, and the outgassing of the supports can be made negligible. The film vessel is shown in Fig. 1. A small cylindrical piece of pure carbon (*A*) is supported on a tungsten rod (*B*) so that its tip is within a one-turn tungsten coil cathode (*C*). The cathode is heated to a controlled temperature by means of a 'Variac' and step-down transformer, and a positive potential of 500–2,000 V. is used to accelerate the emitted electrons to the carbon anode. The tungsten support is shielded from bombardment at high anode potentials by a repelling guard electrode (*D*). Depending on the size of the carbon anode a power of about 40 W. is sufficient for evaporation, after prolonged outgassing with a slightly reduced power. As a consequence of the small size of the anode and its almost complete evaporation the power dissipated within the silica film vessel during evaporation is much less than before while film thicknesses are considerably greater. Films as heavy as 50 mgm. have been obtained, but there is a tendency for such thick films to peel from the walls of the vessel.

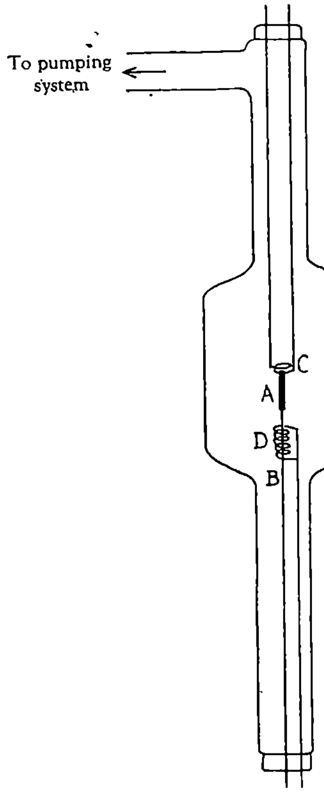

Fig. 1. Diagram of vessel used for carbon evaporation

A krypton isotherm, obtained at −196° C., on a film weighing 11·8 mgm. deposited without cooling the silica bulb, is shown in Fig. 2 with the corresponding B.E.T. plot. An almost equally straight line is

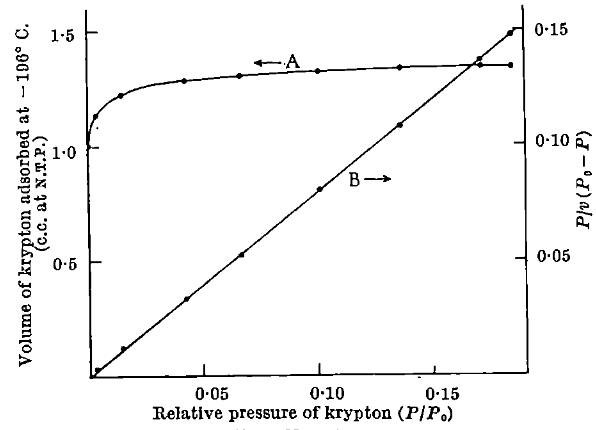

Fig. 2. Absorption of krypton on a carbon film

obtained from a Langmuir plot, as reported for graphite[2]. The B.E.T. monolayer volume is 1·24 c.c. at N.T.P., Taking 20 Å.[2] for the effective cross-sectional area of a krypton atom, the film area is 6·67 m.^{2} or 565 m.^{2}gm.$^{-1}$. Films of this area, which is such that contamination hazards are much less severe than before, are readily prepared by the new method. The specific surface area is some ten times greater than that of the thinner films prepared by Sykes and Thomas, and is only slightly affected by baking at 550° C. A study of the relation of film area to film thickness is under way.

The Marangoni Effect and Liquid/Liquid Coalescence

The rate of coalescence of liquid drops (phase 1) suspended in an immiscible liquid (phase 2) has been shown to increase when a third component, soluble in both phases, diffuses out of the drop[1–5], and vice versa. This behaviour has been attributed to the Marangoni effect[6], whereby interfacial flow is established by gradients in interfacial tension causing an increase in one case, and a decrease in the other, of the rate of thinning of the phase-2 film separating the coalescing interfaces.

We have studied the buoyant rise of a drop of water (phase 1) through cinnamaldehyde (phase 2) to a flat phase 1/phase 2 interface, using an interferometric method[8] to measure the rate of thinning $-(\mathrm{d}h/\mathrm{d}t)$ of the intervening phase-2 film. For drops 650μ diam., the thinning followed the relation[3]:

$$-\frac{\mathrm{d}h}{\mathrm{d}t} = kh^3$$

Table 1 lists experimental values of k and the corresponding values of the mean rest time $\bar{\tau}$ (ref. 3), which offer strong support of the foregoing hypothesis. Similar, but less complete, results were obtained from the system water/diphenyl sulphide.

Table 1

	$\bar{\tau}$ sec.	$10^8 k$ cm.$^{-2}$ sec.$^{-1}$
1 per cent acetone in phase 1	5·3	$\geqslant 3$
Pure system	8·1	3·0
1 per cent acetone in phase 2	12·0	2·0

The film drainage was uniform and symmetrical in each case, and the minimum thickness of the film at rupture was < 500 Å. Lateral oscillations, or 'kicks'[9–11], were observed during the rise of a drop of water through cinnamaldehyde containing 1 per cent acetone. The oscillation became more marked as the drop approached the interface and continued during the early period of film thinning. Despite the fact that kicks were observed to propel the drop distances of several diameters on the interface, the circular patterns of interference colours and rings were undisturbed, indicating that film thinning continued at a uniform rate.

This work was conducted with financial assistance from the Defence Research Board of Canada (*DRB* grant 9510–05).

Formation of Calcium Chloraluminate by Interaction of Portland Cement with Sea-water and Chloride Solutions

The effect of chloride-containing solutions on Portland cement has received relatively little attention. Batta[1] and Thorvaldson[2] noted that addition of chloride ions to solutions containing sulphate reduced or inhibited the expansion of concrete and mortar bars. Batta attributed this effect to the increased solubility of gypsum and calcium sulphoaluminate in chloride solutions.

In the present investigation prisms of dilute pastes of Portland cement I and V and of mortar were exposed to various attacking solutions, including Mediterranean sea-water, solutions containing 3 per cent sodium chloride + 0·4 per cent magnesium sulphate (artificial sea-water), 3 per cent sodium chloride + 0·4 per cent sodium sulphate, 0·4 per cent magnesium sulphate, 0·4 per cent sodium sulphate, 3 per cent sodium chloride and 3 per cent magnesium chloride respectively and water from the Dead Sea. The products after different reaction times were identified by X-ray powder methods and simultaneously the expansion of duplicate prisms was measured.

Contrary to observations of Batta and Thorvaldson, addition of chloride ions to solutions containing sulphate was found to increase expansion of cement and mortar bars in all the present experiments. Expansion in sodium chloride solution only slightly exceeded that in distilled water. A considerable increase of volume was observed in magnesium chloride solution but can probably be attributed to the accelerated hydration caused by the reaction of magnesium ions with calcium hydroxide and hydrated calcium silicates of the cement.

X-ray patterns of all samples exposed to chloride-containing solutions showed, besides many other lines, a strong one at 7·90–7·97 Å. It was invariably observed independent of any other components present and was attributed to $3CaO.Al_2O_3.CaCl_2.10H_2O$ (A.S.T.M. card No. 2–0081). This was confirmed by direct comparison of the X-ray patterns with that of synthetic material.

The amount of chloraluminate formed is appreciable, increasing steadily with time of exposure of the bars to chloride solutions. The variations observed in the longest spacing, though small, are genuine and probably correspond to minor changes in composition.

The effect of the formation of chloraluminate on the expansion of cement is uncertain. The specific gravity of $3CaO.Al_2O_3.CaCl_2.10H_2O$ (1·89) is lower than that of gypsum or hydrated calcium silicates, but higher than that of $3CaO.Al_2O_3.3CaSO_4.31H_2O$. Moderately increased expansion in chloride-containing solutions might thus be anticipated, in agreement with the majority of the present experiments. However, the possible effect of chloride ions on the solubility of calcium sulphoaluminate, which was detected on all the photographs, and on its further course of reaction (to be discussed elsewhere) cannot be neglected.

The discrepancy between our results and those of Batta and Thorvaldson may perhaps be interpreted in terms of two competing factors : (*a*) the crystallization of chloraluminate; (*b*) the effect of chloride ions on the stability of other components, particularly sulphoaluminate. Their relative importance depends on the experimental conditions and remains to be investigated.

The very small expansion of cement bars in sodium chloride solution indicates that the increase of volume accompanying chloraluminate crystallization alone was largely absorbed by the pores. Only in the presence of sulphate solutions was excessive expansion observed, due to the combined effect of the formation of calcium chloraluminate and calcium sulphoaluminate.

Failure of previous investigators to detect chloraluminate in the course of their many studies of attack of cement by sea water may perhaps be attributed to the lack of X-ray data in relevant cases.

We wish to express our thanks to the Ford Foundation for a grant which made this research possible.

Chromium, Uranium, Tungsten and Nickel Complexes of Thioglycolic Acid

The most commonly available of the thiol-acids is thioglycolic acid, also known as mercapto-acetic acid. This reagent is favoured by analytical chemists in research and industry[1–3] for the colorimetric estimation of iron in micro-quantities because of certain advantages it offers[4,5]. In this Laboratory this reagent had been used in the annulus method for separation and detection of chromium and titanium on a filter paper[6].

Chromium has been usually determined colorimetrically, for example, with diphenyl carbazide, after oxidizing it to the hexavalent state, but the use of thioglycolic acid has the distinct advantage that chromium can be present in the original solution in the hexa- or tri-valent state. The use of this complexing agent has been extended for the colorimetric determination of the other elements of Group VI *A*, namely, tungsten and uranium, and also to nickel which frequently occurs in admixture with these. This reagent has already been used for the estimation of molybdenum[7] alone or in the presence of

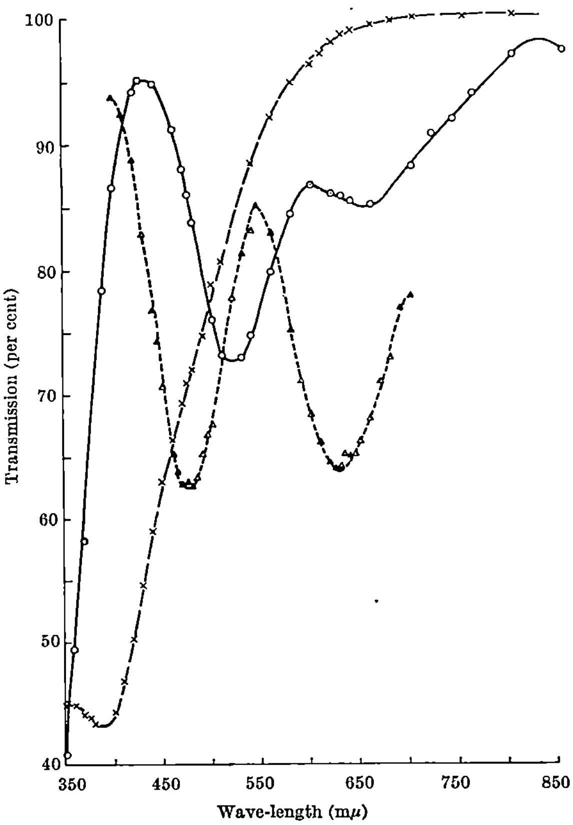

Fig. 1. Transmission curves of the thioglycolic acid complexes. ⍋, chromium, 30 μgm. Cr/ml. at *p*H 9, light-path 40 mm.; ×, uranium, 10 μgm. U/ml. at *p*H 7, light-path 40 mm.; ○, nickel, 23·5 μgm. Ni/ml. at *p*H 7, light-path 40 mm.

Table 1

	Chromium	Uranium	Tungsten	Nickel
Colour of complex in acidic medium	Violet	Colourless	Yellowish	Yellowish-green
Absorption maxima	350 mμ (*p*H 2)	—	(10^{-3} *M* soln.)	(10^{-2} *M* soln.) (*p*H 2)
Colour of complex in alkaline medium	Green	Orange	Colourless	Pink
Working range of *p*H	(6–9)	(6·5–7·5)	(2·5–5·5)	(7–9)
Absorption maxima	*630 mμ and 475 mμ	388 mμ	305 mμ	522 mμ
Molar absorbency index (A_M)	$1·95 \times 10^2$ (on either max.)	23×10^2	53×10^2	$0·98 \times 10^2$
Approximate ratio of A_M	2	25	55	1
Limits of determination (absorptiometrically)	$(1–75) \times 10^{-4}$ *M*	$(2–75) \times 10^{-5}$ *M*	$(4–40) \times 10^{-6}$ *M*	$(2–20) \times 10^{-4}$ *M*
Polarographic $E_{1/2}$ versus S.C.E.	—	—	—	−0·68 V.
Limits of determination (polarographically)	—	—	—	$(0·2–2·0) \times 10^{-4}$ *M*

* In industrial analysis one could use a Spekker absorptiometer and a combined filter (ref. 12) consisting of one filter from Chance's glass-filter set *H*455 and one from Ilford gelatin-filter, namely (OB_2 + 602) and (OY_2 + 607) respectively for 475 mμ and 630 mμ over the same range of concentration with a 40-mm. absorption cell.

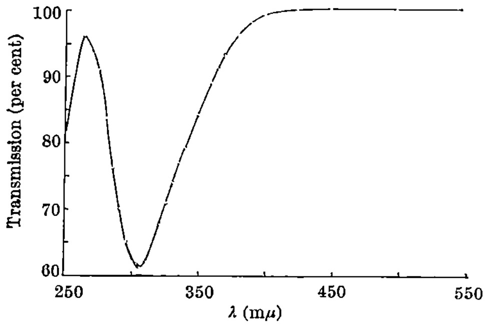

Fig. 2. Transmission curve of thioglycolic acid complex of tungsten. ~ 15 μgm. W/ml. at *p*H 3·5, light-path 10 mm.

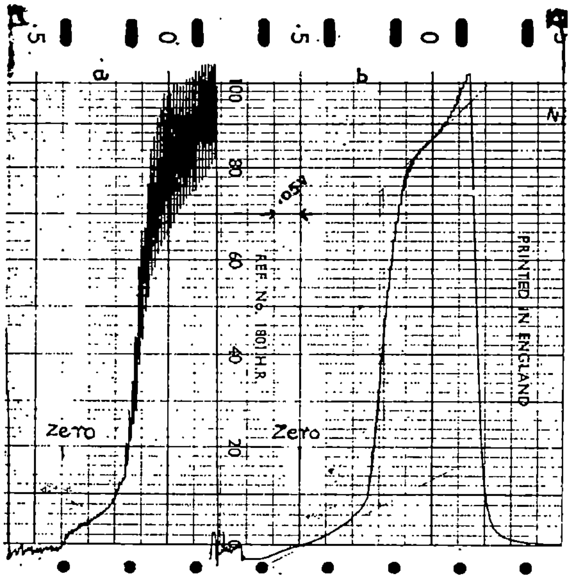

Fig. 3. Cathodic polarographic wave of nickel (12·8 p.p.m.) in ammonium thioglycolate supporting electrolyte at *p*H 8. Sensitivity 2 × 1 μamp./50 division (*a*) without damping, (*b*) at damping position (3) of the Tinsley polarograph mark 19

tungsten[8]. Thioglycolic acid was used[9] as a complexing agent for uranium, but the effect of variation of *p*H has been critically investigated only recently and an absorption maximum reported[10]. The nickel complex has also been investigated polarographically[11] and since the reduction wave is favourably placed at −0·18 V. against a mercury pool, interference from other elements in the polarographic determination of nickel is excluded. The reaction at the dropping mercury electrode involves a two-electron reduction. The wave-height is diffusion-controlled and the temperature coefficient of the wave-height is about 2 per cent per degree rise of temperature. The effect of variation of *p*H and the interference of other ions has been determined in the colorimetric and polarographic determinations of chromium, tungsten, uranium and nickel. Of these, the complexes of thioglycolic acid with chromium, tungsten and nickel have been investigated for the first time.

In a typical determination the solution is treated with excess of reagent on a hot plate and the *p*H of the solution is then adjusted to the required value. After re-heating, the *p*H is checked again. The solution of the complex is then analysed for the respective element. The results of some typical determinations are shown in Table 1. The transmission spectra of different complexes and the reduction wave of the nickel complex[11] with thioglycolic acid are shown in Figs. 1–3.

The complexes of chromium, tungsten, uranium and nickel can be used for the micro-determination of these metals. They are quite stable (the tungsten complex is stable for two weeks), and even a large excess of the thioglycolic acid can be used without any detrimental effect, which is not the case with thiocyanate complexes of tungsten, uranium, etc. Nickel also complexes with *o*-mercaptobenzoic acid, a homologue of thioglycolic acid, which has similar absorption characteristics to nickel thioglycolate. The reagent has been found to be a promising complexing agent for other metals, for example, rhenium, indium, etc. Complete results of these investigations will be communicated later.

I wish to acknowledge the collaboration of Dr. J. A. W. Dalziel, of the Imperial College of Science and Technology, London, in the polarographic investigation of nickel.

BIOCHEMISTRY

Interaction of Hydrocortisone, the Sulphydryl Group, and the Catechol Amines

Hydrocortisone potentiates the physiological effects of epinephrine and norepinephrine[1]. The mechanism of this action remains obscure. Recently, reaction of oxidation products of the catechol amines with the sulphydryl group has been demonstrated *in vitro*[2,3]. Further *in vitro* studies suggest that the physiological interrelationship between hydrocortisone and the catechol amines may involve the sulphydryl group.

The norepinephrine, cysteine and manganese dioxide used were previously described[2,4]. Steroids were obtained from the Upjohn Co., the Schering Corporation and the Nutritional Biochemical Corporation. After solution of approximately 10 mgm. of hydrocortisone in 1·0 ml. of absolute ethyl alcohol, the concentration was decreased to 500γ per ml. by addition of water. The other steroids studied were used in solution in absolute alcohol only. Other reagents included 2/3 *N* sulphuric acid and 1 *N* sodium hydroxide. Buffers were 0·1 *M* sodium phosphate of *p*H 7·4 and 8·0. Absorbencies were measured in the Beckman *DU* spectrophotometer with tungsten lamp.

The experimental procedure began with the preparation of a solution containing $0·15 \times 10^{-3}$ *M* cysteine and the indicated concentration of hydrocortisone immediately before its utilization. At zero time, 0·5 ml. of 1 *N* sodium hydroxide was added to separate test-tubes containing 2·0-ml. aliquots of this solution. One-half of these tubes were used for the development of noradrenochrome, the other half for the simultaneous measurement of the residual sulphydryl group. At 5-min. intervals after the alkalinization, 0·70 ml. of 2/3 *N* sulphuric acid, 1·0 ml. of 0·1 *M* sodium phosphate buffer of *p*H 7·4, 0·1 ml. of $3·0 \times 10^{-3}$ *M* norepinephrine, and 0·1 gm. of manganese dioxide were added rapidly to an additional tube and oxygen was bubbled vigorously through the solution for 40 sec. 6 min. later, the absorbency of the noradrenochrome formed was measured at 480 mμ. Simultaneously, every 5 min., 0·68 ml. of 2/3 *N* sulphuric acid and 1·0 ml. of 0·1 *M* sodium phosphate buffer of *p*H 8·0 were added to a separate tube. The sulphydryl group was then determined from the absorbency at 412 mμ of the compound formed by Ellman's technique[5]. Parallel tubes with cysteine but without hydrocortisone were used as controls in each case.

Table 1. PERCENTAGE OF THE SULPHYDRYL GROUP OF CYSTEINE REMAINING IN THE FREE STATE AFTER VARIOUS PERIODS OF TIME

Molarity of hydrocortisone			
Molarity of cysteine	6 min.	15 min.	30 min.
0 (auto-oxidation))	91	84	74
½	84	69	47
1	77	58	26
3	60	25	0

Reagent solutions containing 500γ of hydrocortisone per ml. of alcohol alone or per ml. of alcohol and water as described affected the sulphydryl group identically, the effect of the alcohol being negligible. The effects of various concentrations of hydrocortisone upon the sulphydryl group of cysteine in alkaline solution are presented in Table 1. In contrast to hydrocortisone such steroids as progesterone, testosterone and deoxycorticosterone acetate had no effect, while corticosterone was only slightly effective. On the other hand, 17α-hydroxy-11-deoxycorticosterone, cortisone and hydrocortisone acetate had essentially the same effect as hydrocortisone. This action of the steroids was present only in highly alkaline solution. The results for glutathione were similar in direction but considerably less in magnitude than those for cysteine. The amount of noradrenochrome developed from norepinephrine at *p*H 7·4 increased as the free —SH group decreased. The intensity of the pink colour and the absorbency at 480 mμ reflected the disappearance of the sulphydryl group, just as did the Ellman technique.

The experimental evidence suggests that the sulphydryl group of cysteine reacts in alkaline solution on an equimolar basis with many steroids which have a C_{17} side-chain. The reactivity of hydrocortisone acetate indicates that the C_{21} hydroxyl group is not essential. Conversely, the ineffectiveness of progesterone and deoxycorticosterone acetate shows the inadequacy of the C_{20} oxygen alone. The presence of the keto-group on C_{20} and the α-hydroxyl group on the C_{17} position is characteristic of the steroids which react with the sulphydryl group. It is interesting to note that this high reactivity of cortisone and hydrocortisone *in vitro* parallels their strong potentiation of catechol amine action *in vivo*[1].

The increased development of noradrenochrome at *p*H 7·4 as the cysteine disappears is important because it illustrates a possible mechanism of hydrocortisone action *in vivo*. The norepinephrine–cysteine and norepinephrine–glutathione compounds have no effect upon the blood pressure of the dog, according to recent work done at the University of Louisville in conjunction with Dr. K. C. Huang of the Department of Pharmacology. Hence, by preventing combination of cysteine and glutathione with derivatives of the catechol amines, hydrocortisone might direct the metabolic pathways of epinephrine and norepinephrine toward reactions which would intensify and prolong their physiological effects. An enzyme which would facilitate the reaction of the sulphydryl group and hydrocortisone at *p*H 7·4 is not available as yet. The existence of such an enzyme appears to be quite feasible, and search for it *in vivo* is under way.

This investigation was supported by grant No. *M*-2795 (*C*1) from the National Institutes of Health of the U.S. Public Health Service.

Effects of Injections of Some Intermediary Metabolites on the 'Insulin Response' of Normal Rabbits

CONTINUED daily injections of β-hydroxy butyrate in gradually increasing doses has been found to increase initially the insulin content of the pancreases of guinea pigs and then bring about a gradual decrease of active insulin/gm. of pancreas tissue[1]. Similar experiments by Schwartz *et al.*[2] have recently confirmed these findings in both guinea pigs and albino rats. The present communication indicates the effects of some members of the trichloroacetic acid cycle, compared to β-hydroxy butyrate, on the insulin response of normal rabbits.

Pure sodium salts of the metabolites concerned and crystalline insulin solution (Lily) were used in these experiments on healthy normal rabbits. Five rabbits were used in each case and each experiment was repeated twice as in cross-over tests in insulin assay[3]. Each rabbit was allowed one week's rest between experiments.

In one set of experiments sodium salts of the metabolites concerned (dissolved in 5 c.c. of normal saline) were injected in fasting (18 hr.) normal rabbits and the blood sugar-level studied at hourly intervals for a period of 3 hr. In a second set of experiments the metabolites concerned were mixed *in vitro* with 2 units of insulin (diluted to 5 c.c. with normal saline), the mixture incubated at 37° C. for 30 min., and the clear solution injected in one leg of the rabbits. The blood sugar-level was then examined as in the previous case. In a third set of experiments the metabolites were injected simultaneously but separately with 2 units of insulin in the two legs of the rabbits to study the *in vivo* effect on the insulin response. Control experiments were carried out simultaneously with each set of the above experiments to study the blood sugar response on injection of 2 units of insulin alone. The micro-method of Folin and Malmros[4] was used in estimating blood sugar in samples of blood drawn from the marginal ear veins of the experimental rabbits. The results of these experiments are given in Table 1.

Table 1. EFFECTS OF INJECTIONS OF METABOLITES ON THE INSULIN RESPONSE OF NORMAL RABBITS

S. No.	Substance injected	Average percentage of reductions in blood sugar			
		2 units insulin only	100 mgm. of substance	100 mgm. and 2 units insulin *in vivo*	100 mgm. and 2 units insulin *in vitro*
1	Insulin (control)	56·9 ± 3·46	—	—	—
2	Sodium pyruvate	—	8·98 ± 1·1	66·78 ± 3·2	50·8 ± 3·4
3	Sodium β-hydroxybutyrate	—	12·84 ± 1·5	66·75 ± 3·5	53·43 ± 2·1
4	Sodium isocitrate	—	17·12 ± 2·0	57·51 ± 3·3	49·0 ± 2·8
5	Sodium succinate	—	22·54 ± 1·8	56·14 ± 3·2	46·0 ± 3·0
6	Sodium citrate	—	30·34 ± 3·0	51·98 ± 3·1	40·83 ± 2·8

From Table 1 it is apparent that all these metabolites when injected alone in normal fasting rabbits produce a hypoglycæmic response which may be due to their stimulating effect, direct or indirect, on the *B*-cells of the islets of Langerhans, initiating a secretion of insulin. This stimulation for the same amount of substance injected is greatest in case of citrate and is progressively lesser in the following order: citrate–succinate–isocitrate–β-hydroxy butyrate–pyruvate.

The results of *in vivo* experiments suggest that while the stimulating power of β-hydroxy butyrate and pyruvate are independent of the presence of exogenous insulin in the system, the other three metabolites, namely, citrate, succinate and isocitrate, seem to lose their stimulating power in presence of exogenous insulin in the system. The results of *in vitro* experiments suggest that while β-hydroxy butyrate and pyruvate have no effect on the biological potency of exogenous insulin, the other three metabolites, namely, citrate, succinate and isocitrate, bring about a decrease in the biological potency of exogenous insulin in similar circumstances, namely, *in vitro* mixing and incubation at 37° C. for 30 min. before injection.

Estimation of Protein in Cellular Material

PROTEIN content is a widely used reference value for microbial growth yield, enzyme activity, and other biochemical quantities. The assay of dissolved protein is relatively easy, being accomplished by measuring the absorbence at 280 mμ or by use of the biuret reagent, etc. The assay of protein in cellular material involves a time-consuming digestion (Kjeldahl method). In addition to being slow, this method is non-specific and does not immediately distinguish between proteins and other nitrogen compounds.

The method reported here is based on the fact that most solid protein samples, including precipitates made with trichloroacetic acid or by heat coagulation, are soluble in a dilute base. By using half-strength biuret reagent (containing 0·4 *M* sodium hydroxide) it is possible to extract and afterwards measure rapidly.

Cell materials seem to fit three categories with regard to method: (1) Require no previous treatment (most bacteria). (2) Chlorophyllous cells (algae and leaf tissue) require extraction with 70–80 per cent ethanol to remove pigments. (3) Cells that resist base extraction of their protein (yeast and algae). These require pre-treatment with 0·5 *M* perchloric acid. The reason for this is not clear but may be related to cell wall thickness or to covalent bonds existing between the protein and structural polymers. Nevertheless, pre-treatment with perchloric acid does make reproducible protein extraction possible. (The bean leaf tissue does not require pre-treatment with perchloric acid but was so treated for other reasons.)

Wet cell masses are collected by centrifugation and washed, if necessary, to remove any large amount of reducing sugar which may be present in the medium. (The cupric ions in the biuret reagent are susceptible to reduction and precipitation as cuprous oxide.) The centrifuged solids are suspended in at least 10 vol. of water to which is added an equal volume of biuret reagent[1]. This mixture is allowed to stand at room temperature for one hour with occasional stirring. The insoluble residue is removed by centrifugation, leaving a water-clear, purple solution. Readings are made in tubes (16 mm. int. diam.) against a reagent blank in a Coleman spectrophotometer at 540 mμ.

Proteins from different sources give somewhat different colour yields. Thus, an absolute protein measurement must be made if it is necessary to calibrate the method. (Such calibration is not necessary when comparisons are to be made only between samples of the same biological origin.) In the examples presented here the protein was first read as a biuret colour intensity and then precipitated with trichloroacetic acid. The precipitate is analysed via Kjeldahl technique and the usual factor of 6·25 mgm. protein/mgm. N is applied. It is assumed that trichloroacetic acid brings down all the protein. This is apparently borne out by analyses which show that only a small amount of nitrogen (attributable to compounds of low molecular weight) remains in the frac-

Table 1. COLOUR YIELDS AND EXTRACTION EFFICIENCY OF CELLULAR PROTEIN WITH BIURET REAGENT

Cell material	Colour yield O.D. × ml./mgm. protein	Percentage of TCA-insoluble nitrogen in extractable nitrogen	Percentage of non-extractable nitrogen (based on extractable plus non-extractable nitrogen)
Bean leaf* *Phaseolus vulgaris*	0·59	96	3
Algae* *Chlorella vulgaris*	0·55	83	29
Yeast† *Saccharomyces cerevisiae*	0·54	91	24
Bacteria *Azotobacter vinelandii*	0·48	84	10
Bacteria *Escherichia coli*	0·39	85	22

* Pre-treated with ethanol and then perchloric acid.
† Pre-treated with perchloric acid.

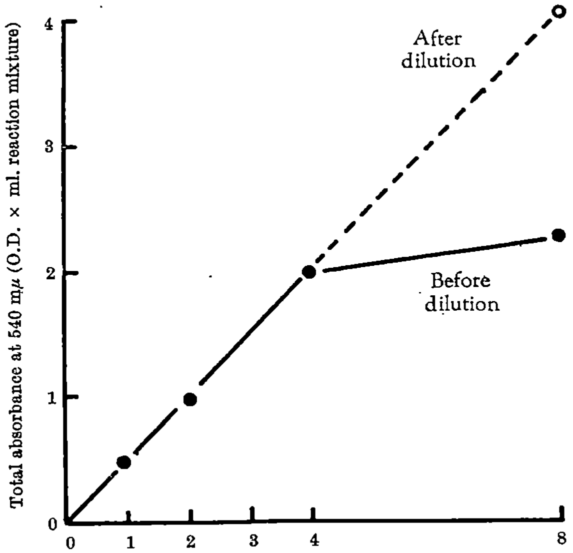

Fig. 1. Linearity of biuret colour intensity versus protein concentration (*A. vinelandii*)

tion soluble in trichloroacetic acid. Table 1 illustrates some representative results.

The biuret reagent does not have a wide range of linearity. Furthermore, the solubilized protein from different sources appears to have individual ranges of linearity. For both these reasons it is well to establish first a colour-concentration curve for each type of material. Fortunately, it is possible to dilute non-linear samples with a 1 : 1 mixture of water and reagent. After an additional incubation of 30 min. the colour is found to be proportional to protein (Fig. 1).

Extraction of protein may not be quantitative for all materials (Table 1). This may not be a serious problem to persons concerned with only one type of cell, especially when repeated extractions yield results within ±5 per cent. In the case of yeast cells the unextracted nitrogen may be a 'fungal chitin'. In the case of *E. coli* at least some of the unextracted nitrogen is protein, as judged by the biuret-purple colour of the remaining solids. This particular extraction might be made more quantitative by pre-treatment with 0·5 *M* perchloric acid.

Chlorophyll-containing materials are extracted in boiling 70 or 80 per cent ethanol until colourless. The solids are then extracted with perchloric acid and/or biuret reagent.

The centrifuged material is suspended in at least 10 vol. 0·5 *M* perchloric acid and incubated, with occasional stirring, at 80° for 90 min. (This is essentially the method used by Basler and Commoner for extraction of ribonucleic acid[2].)

The combined loss of protein due to the treatments with dilute biuret reagent and 0·5 *M* perchloric acid is less than 10 per cent (ref. 3).

1-(Indole-3-acetyl)-β-D-Glucose, a New Compound in the Metabolism of Indole-3-acetic Acid in Plants

STUDYING the fate of exogenously applied indole-3-acetic acid (IAA) in pea epicotyls, we observed, besides indoleacetylaspartic acid[1] (IAAsp), a trace amount of a compound which showed definitely indole reactive properties and which was split on alkaline hydrolysis into IAA. The amount of this metabolite proved too small for identification, therefore we carried out a rough survey on one species from 20 plant families using 2-^{14}C IAA in the hope of finding an accumulation of this metabolite. This unknown compound was found in the leaves of the monocotyledonous plant *Colchicum neapolitanum* Ten. to about 65 per cent of the total amount of IAA taken up, the rest being unchanged IAA (20 per cent) and minor components (Fig. 1, top). IAAsp was detected, if at all, only in very small quantities. In order to isolate a larger amount of this compound, 70 gm. of mature *Colchicum* leaves were cut into pieces and incubated with 1 litre of a 4×10^{-4} *M* solution of IAA for 24 hr. with good aeration. The compound was extracted from the leaves with boiling 80 per cent aqueous ethanol; the extract was then concentrated to a small volume and made up to a powder with 'Hyflo supercel' and then extracted in a Soxhlet-type extractor for 6 hr. with ether. The ether containing only the IAA was discarded, and extraction continued with ethyl acetate for another 6 hr. This solution was taken to dryness and the residue containing the compound chromatographed as streaks on Whatman No. 3 paper in *n*-butanol / glacial acetic acid / water (5 : 1 : 2·2, R_F 0·56) and in *iso*propanol / benzine / water (55 : 30 : 11, R_F 0·39). By elution and re-chromatography between the two solvents, the derivative could be purified and resulted finally in 6·05 mgm. of a highly purified, non-crystalline material. The compound was located on the paper by spraying with *p*-dimethylaminobenzaldehyde.

Hydrolysis of the material with 1 *N* potassium hydroxide at room temperature led to the hydrolysis products IAA and a carbohydrate chromatographically identical with glucose. Acid hydrolysis with 2 *N* hydrochloric acid at 100° C. gave the same result. The compound was split with hydroxylamine to form indoleacetyl hydroxamic acid, chromatographically identical with synthetic hydroxamate, thus showing an ester linkage.

The ultra-violet absorption spectrum of the compound showed a minimum at 248 mμ, a maximum at 278 mμ and a shoulder at 288 mμ. Equimolar solutions of IAA and the unknown had the same extinction coefficient at 280 mμ while the differences in the spectra of the two compounds showed a maximum at 240 mμ ($E = 2·9 \times 10^3$). This spectrum closely resembles that of indoleacetyl-thioesters[2], thus again suggesting an ester linkage between IAA and glucose. On treatment with the Salkowski reagent[3], the resulting colour of the compound was shifted from the IAA peak ($\lambda_{max.}$ 535) towards the longer wave-length ($\lambda_{max.}$ 545); indolethylacetate shows $\lambda_{max.}$ 555 and indoleacetyl-thioesters, $\lambda_{max.}$ 575. Maximal colour intensity was attained in each case 11 min. after the addition of the reagent. Aliquots of the compound were analysed for functional groups and the ratio of the assays was IAA / ester linkage / glucose = 1·00 : 1·01 : 1·00. The IAA concentration was based on the absorption at 280 mμ, glucose was determined with the anthrone reagent[4] and the ester linkage with

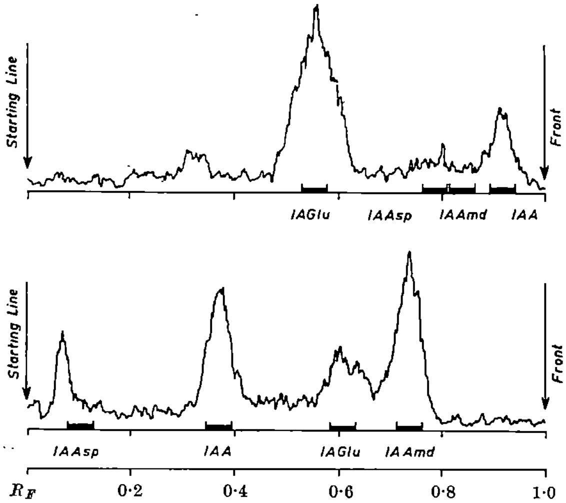

Fig. 1. (Top): Scanning record of a chromatogram of an alcoholic leaf-extract after 24 hr. treatment with 10^{-4} *M* 2-^{14}C IAA developed in *n*-butanol / acetic acid / water (5 : 1 : 2·2). (Bottom): Scanning record of a chromatogram with the same extract developed in *iso*propanol / NH_3 (25 per cent) / water (8 : 1 : 1)

the hydroxamic acid test[5]. In the absence of free IAA, 1 μM of indoleacetyl hydroxamate in 5 ml. test solution gives an extinction of 0·230 Beckman unit at 540 mμ. On the basis of this analysis the compound represents a glucose ester of IAA. To determine which carbon atom of glucose is esterified, the compound was subjected to the action of β-glucosidase (K^+, acetate buffer, *p*H 5·0) and was split quantitatively by this enzyme. The compound lacks reducing properties. These properties are characteristic for an ester linkage in the 1-position of glucose in β-configuration. I am therefore able to assign to the ester the structure of 1-(indole-3-acetyl)-β-D-glucose (IAGlu). (During the preparation of this manuscript a tentative identification of this ester was made by Klämbt, H. A. (*Planta*, 56, 618 ; 1961). A critical discussion of this presentation will be left to a further publication.)

The ester is labile towards ammonia. Using ammoniacal *iso*propanol for chromatography resulted in the ammonolysis of 57 per cent and in the hydrolysis of 13 per cent of the ester, a total of 70 per cent of the ester being destroyed. The predominant reaction product was indoleacetamide (IAAmd) (Fig. 1, bottom). IAGlu is also split in bicarbonate solution containing ammonia salts to yield IAA and IAAmd. I therefore assume that the reports in literature on the occurrence of IAAmd in plants are erroneous and probably due to chromatographic and isolation artefacts. This behaviour of IAGlu is in accordance with the ammonolysis of indoleacetylglucosiduronic acid[6].

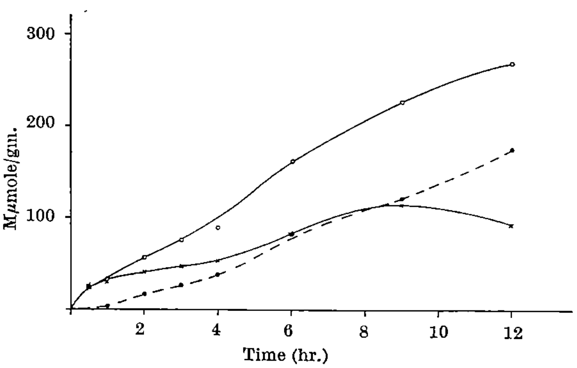

Fig. 2. The uptake of IAA from solution and accumulation of IAA and IAGlu in leaf-disks of *C. neapolitanum* during 12 hr. of incubation in a 5×10^{-5} *M* 2-^{14}C IAA solution. ○, Total uptake of IAA from external solution; ●, IAGlu, and ×, IAA, accumulating in leaf-disks

The uptake and metabolism of IAA by *Colchicum* leaf-disks is shown in Fig. 2. The uptake of IAA during 12 hr. was fairly constant. The quantity of IAA in the free form rises during the first 9 hr. and then falls off again. In contrast to experiments with pea epicotyls[7], the IAA concentration in this leaf tissue exceeded the concentration in solution by a factor of more than 2, a fact which suggests a metabolic uptake of the acid. Unlike the conjugation of IAA with aspartic acid there was no lag-period in the conjugation of IAA with glucose. The synthesis of IAGlu certainly involves a transference of glucose from uridinediphosphoglucose on to IAA.

Besides the conjugation with aspartic acid, I therefore assume a second de-toxification mechanism of aromatic acids in plants, the conjugation with glucose. Both types of de-toxification may operate simultaneously or one or the other may predominate in different plant species.

IAGlu is a member of the recently discovered group of naturally occurring sugar esters[8], and is active in the *Avena* cylinder-test.

This work was supported by the Bundesministerium für Atomkernenergie und Wasserwirtschaft.

2-^{14}C IAA was a gift from Dr. H. Simon, for which we are very grateful.

Effect of Amino-Acid Esters on the Growth of Fibroblast Cultures

Perri *et al.*[1] demonstrated that amino-acid esters inhibit the growth of bacteria. Simultaneously with this finding, Horváth *et al.* described the inhibition of certain amino-acid esters on the adaptive amylase production of *Penicillium chrysogenum*[2]. Fehér *et al.* demonstrated that DL-methionine-ethyl ester caused liver lesions[3].

The mechanism of this inhibition has not yet been examined, but it is supposed that because of the bound carboxyl group the amino group becomes more reactive and thus the activated amino-acid reacts with the ester instead of the intact amino-acid.

The inhibition of ethionine on growth and protein synthesis is well known. We supposed that this effect is unable to diminish even after the esterification of ethionine. To prove this supposition, we attempted to compare the inhibition of growth by ethionine and ethionine ethyl ester on cell cultures.

The pure fibroblast culture used in our experiments was cultivated in tubes of 3 ml. volume described elsewhere[4]. An ocular micrometer was used to measure the radii of the cell cultures. The basis of comparison was the total of radii measured in four directions. The basic growth of the cultures was measured always on the third day after the inoculation of the cells and the substance investigated was added in a volume of 0·1 ml. to the culture medium. The difference between the basic growth and that on the third day of the experimental period characterized the activity of the substances examined.

In the first experiment we investigated whether certain amino-acid esters inhibit the growth of tissue cultures similarly to bacteria described previously[4,5]. 1·5 m.mole/l. methionine ethyl ester was added to the culture medium. An inhibition of more than 50 per cent was observed (Table 1). The inhibition of methionine anti-metabolites, as is well known, can be prevented by methionine or glutamine[3,6]. Next we added 3 m.mole/l. methionine or glutamine to the culture medium, which prevented the inhibition of methionine ethyl ester about 50 per cent. Methionine ethyl ester behaves thus like other methionine antagonists and its growth inhibition may be prevented by addition of methionine to fibroblast cultures.

Table 1. EFFECT OF AMINO-ACID ESTERS ON THE GROWTH OF FIBROBLAST CULTURES

Added substance	No. of cultures	Basic growth	Growth after addition of substance	Growth in percentage compared with the control
Control	520	24·0 ± 5·5	45·0 ± 9·2	100
DL-Methionine-ethyl ester, 0·15 m*M*	440	24·3 ± 5·3	34·0 ± 7·1	45·7
DL-Methionine-ethyl ester, 0·15 m*M* + DL-Methionine, 0·3	385	22·1 ± 4·0	37·4 ± 6·2	72·5
Control	114	29·4 ± 4·4	52·2 ± 5·3	100
DL-Methionine-ethyl ester, 0·15 m*M*	120	29·8 ± 3·8	37·2 ± 5·0	32·0
DL-Methionine-ethyl ester, 0·15 m*M* + DL-Glutamine, 0·3 m*M*	126	28·7 ± 5·7	43·4 ± 6·9	64·5
Control	343	20·4 ± 3·6	36·0 ± 6·9	100
DL-Ethionine-ethyl ester, 1·5 m*M*	163	19·5 ± 4·1	33·7 ± 6·2	89·0
DL-Ethionine, 1·5 m*M*	202	19·6 ± 3·9	25·9 ± 5·4	39·4
DL-Ethionine, 1·5 m*M* + DL-Ethionine-ethyl ester, 1·5 m*M*	209	18·9 ± 3·7	31·8 ± 6·7	80·5

Further, we studied the ethionine sensitivity of the culture. As shown in Table 1, 1·5 m.mole/l. ethionine causes a significant inhibition of growth.

On the basis of the hypothesis discussed here, it might have been expected that ethionine ethyl ester added in the same concentration of ethionine produces inhibition of growth similar to ethionine or methionine ethyl ester. In the next experimental series we therefore added ethionine ethyl ester in a concentration of 1·5 m.mole/l. to the culture medium. The ester was practically ineffective, the inhibition being only 11 per cent.

Due to simultaneous addition of a double amount of ethionine ethyl ester (3 m.mole/l.) and of 1·5 m.mole/l. of ethionine, the inhibition of growth by ethionine decreased about 50 per cent.

It seems that the inhibition of methionine ethyl ester was of a competitive character, because it could be prevented by addition of methionine in greater amounts. In contrast with expectation, however, the inhibition of the ethionine and ethionine ethyl ester added at the same time is not additive, but the ester nearly prevents the inhibition. The quantitative conditions point to competitive inhibition, too, although in this case it is the ester that prevents the effect of the amino-acid.

Our experiments do not explain the mechanism of inhibition of amino-acid ester, but it seems that the hypothesis that inhibition was induced only by the increased reactivity of the amino-group is dubious.

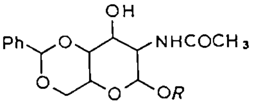
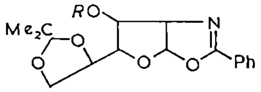
A Convenient Synthesis of Muramic Acid and Other 3-O-Ethers of D-Glucosamine

3-O-ETHERS of D-glucosamine, including muramic acid (3-O-carboxyethyl-D-glucosamine, a component of bacterial cells walls), have been prepared[1-4] from the intermediate I (*R* = Me or Et)[5]. We have applied the Williamson ether synthesis to the intermediate II (*R* = H)[6] and have prepared muramic acid, 3-O-methyl- and 3-O-carboxymethyl-D-glucosamines by this procedure. The intermediate (II) is readily prepared in good yield by a two-stage process, whereas the preparation of substance I requires three steps and a separation of the α and β anomers[7,8].



(I)



(II)

Compound II (*R* = H) was prepared by the method of Konstas, Photaki and Zervas[6] except that the crude N-benzoyl-D-glucosamine which separates from the reaction mixture was used (after thorough drying over phosphorus pentoxide *in vacuo*) without further purification. The overall yield of crystalline II (*R* = H, m.p. 158–160°) from glucosamine hydrochloride was 55 per cent. After recrystallization from ethyl acetate, the compound had the following characteristics: m.p. 160–162°; $[\alpha]_D^{19} + 6°$ (*c*, 2 in chloroform); infra-red absorption (potassium chloride disk) 1,648 cm.$^{-1}$ (C=N stretching vibration).

For the synthesis of muramic acid, intermediate II (*R* = H) (35 gm.) was treated with sodium hydride (2·9 gm.) in refluxing tetrahydrofuran (450 ml., sodium-dried, peroxide-free) for 2 hr. To the cooled solution of the sodio derivative was added dried, redistilled, ethyl DL-α-bromopropionate (35 gm.). There was an immediate precipitation of sodium bromide, and after the initial exothermic reaction had subsided, refluxing was continued for another hour. After cooling, the solution was filtered and the tetrahydrofuran and excess bromo-ester were removed by evaporation under reduced pressure. The crude product was saponified by warming for 5 min. at 50° in a mixture of water (35 ml.), methanol (35 ml.) and sodium hydroxide (8 gm.). This solution was then diluted with water (350 ml.), saturated with potassium chloride and extracted with ether to remove any unreacted intermediate. The aqueous solution containing the sodium salts of the D- and L-ethers II ($R = \text{—CHMe.COOH}$) was carefully acidified to *p*H 4 with normal hydrochloric acid and the free acids (35 gm., 81 per cent) which were precipitated were filtered, washed with water and dried.

The mixed acids (32 gm.) were heated in refluxing benzene (200 ml.) for 15 min., the insoluble material removed by filtration and the filtrate allowed to stand at room temperature overnight before refiltering. The combined benzene-insoluble materials (10·6 gm.) were recrystallized from hot benzene, giving crystals, m.p. 208–210°, $[\alpha]^{20}_D - 26°$ (*c*, 2 in chloroform); infra-red absorption 1,635 cm.$^{-1}$ (C = N stretching vibration) and 1,705 cm.$^{-1}$ (C = O vibration), and analytical figures agreeing with those for the ether II ($R = \text{—CHMe—COOH}$). Acid hydrolysis in refluxing 2·7 *N* hydrochloric acid for 4 hr. followed by chromatography in phenol–water, 3 : 1 (w/w), revealed a ninhydrin-positive spot with R_F = 0·46 corresponding to the isomer of muramic acid[2].

The benzene solution of the soluble acids (21·4 gm.) was evaporated to 100 ml. and on standing at room temperature needle crystals (13 gm., m.p. approx. 160°) separated. Most of this material dissolved readily in warm ethyl acetate (5 ml./gm.) and filtration removed some of the isomer of m.p. 208–210°. On cooling and seeding, large needle crystals (5 gm.) separated. These had m.p. 163–164°; $[\alpha]^{20}_D + 65°$ (*c*, 2 in chloroform); infra-red absorption 1,635 cm.$^{-1}$ (C = N stretching) and 1,725 cm.$^{-1}$ (C = O vibration) and analytical figures agreeing with those for the ether II ($R = \text{—CHMe—COOH}$). Hydrolysis and chromatography as above, gave one spot R_F = 0·55 corresponding to muramic acid obtained from natural sources.

The acids remaining in the mother liquors were converted to the S-benzylthiouronium salts and recrystallization of the product from 20 per cent methanol in water gave 8 gm. of salt, m.p. 134–136°. On decomposition this gave 5·1 gm. of the acid m.p. 163–164°. (The S-benzylthiouronium salt of the acid m.p. 208–210° has not been obtained in the crystalline state.)

The acid of m.p. 163–164° (10 gm.) was hydrolysed in refluxing 2·7 *N* hydrochloric acid for 4 hr., the benzoic acid removed from the cooled hydrolysate by ether extraction and the hydrochloric acid removed by evaporation under reduced pressure. The residue was dissolved in water and 'Amberlite *IR*–*4B*' (OH form) added until the solution was at *p*H 6. After filtration, the aqueous solution was evaporated to dryness and the crystalline product (6·4 gm., 90 per cent based on muramic acid monohydrate) was recrystallized from water/ethanol. The product m.p. 150–151° (decomp.); $[\alpha]^{22}_D + 144°$ (4 min.) falling to + 112° (23 hr.) (*c*, 2 in water) gave satisfactory analytical figures for anhydrous muramic acid after drying for 6 hr. at 60° *in vacuo* over phosphorus pentoxide.

By a similar procedure, the carboxymethyl ether II ($R = \text{—CH}_2\text{.COOH}$) was prepared by the action of ethyl bromoacetate on the sodio derivative of the intermediate II (R = H). This had the following characteristics: m.p. 185–186° (from ethyl acetate); $[\alpha]^{19}_D - 22°$ (*c*, 2 in chloroform); infra-red absorption 1,635 cm.$^{-1}$ (C = N) stretching), and 1,725 cm.$^{-1}$ (C = O). The compound was hydrolysed and the product worked up as for muramic acid. The 3-O-carboxymethyl-D-glucosamine was recrystallized from water/ethanol, giving needle crystals m.p. 163–164° (decomp.); $[\alpha]^{22}_D + 130°$ (6 min.) falling to + 102° (24 hr.) (*c*, 2 in water). After drying for 6 hr. at 60° *in vacuo* over phosphorus pentoxide satisfactory analytical figures for the anhydrous material were obtained.

The reaction of methyl iodide with the sodio derivative of the intermediate gave the methyl ether II ($R = \text{—CH}_3$) in 90 per cent yield; m.p. 117–119° (from methanol); $[\alpha]^{20}_D - 15{\cdot}5°$ (*c*, 2 in chloroform); infra-red absorption 1,647 cm.$^{-1}$ (C = N vibration). This compound was hydrolysed as above and the 3-O-methyl-D-glucosamine hydrochloride recrystallized twice from methanol/acetone; $[\alpha]^{22}_D$ + 112° (4 min.) falling to + 90° (18 hr.) (*c*, 2 in water).

Satisfactory analytical figures were obtained for all compounds described.

Differential Inhibition of Human Serum Cholinesterase with Fluoride: Recognition of Two New Phenotypes

IT has been shown that individuals excessively sensitive to the drug suxamethonium have a reduced level of serum cholinesterase activity, and that this peculiarity is genetically determined[1]. It has also been found that the cholinesterase present in the serum of such suxamethonium-sensitive individuals is qualitatively different from that occurring in most normal people[2]. This difference can be most simply demonstrated by determining the degree of inhibition produced by certain anticholinesterase substances. For example, using 5×10^{-5} M benzoylcholine as substrate and 10^{-5} M dibucaine as inhibitor under standard conditions, the enzyme in most normal sera shows about 80 per cent inhibition, while that in sera from suxamethonium-sensitive individuals shows only about 20 per cent inhibition. The percentage inhibition obtained under these conditions has been called the dibucaine number (D.N.) and this appears to be a constant characteristic for any one individual[3].

If sera from a large random sample of individuals in the general population are examined, the distribution of D.N. obtained is sharply trimodal, and people can be classified into three phenotypes on this basis[4]. About 97 per cent of the population have the so-called 'usual' phenotype with D.N. clustering around 80, about 3 per cent are of the so-called 'intermediate' phenotype with D.N. clustering around 62, and about

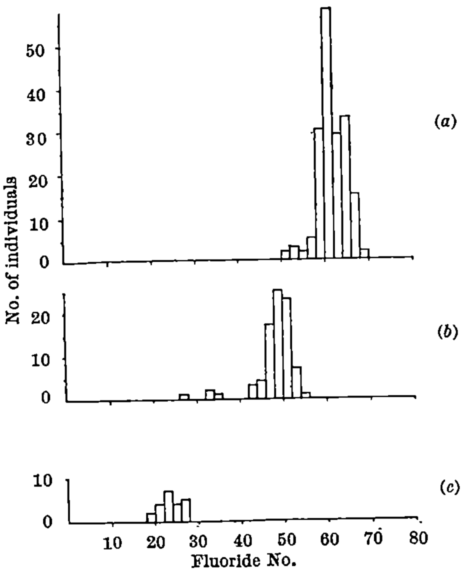

Fig. 1. Distributions of 'fluoride numbers' in individuals of the (a) 'usual', (b) 'intermediate' and (c) 'atypical' phenotypes as defined by dibucaine number determination

1 in 4,000 have the so-called 'atypical' phenotype with D.N. around 20. Suxamethonium-sensitive individuals belong to the 'atypical' phenotype. The three phenotypes are genetically determined. Two allelic genes are thought to be concerned, the 'usual' or normal phenotype being homozygous for one of these, the 'atypical' phenotype being homozygous for the other, and the 'intermediate' phenotype representing the heterozygotes[4,5]. It is likely that in the heterozygotes where both genes are present, both the 'usual' and the 'atypical' forms of the enzyme are synthesized in roughly equal amounts.

Kalow and Davies[6] have shown that a wide variety of inhibitors, but each containing a quaternary ammonium grouping, can be used to demonstrate this differential inhibition of the two enzymes. On the other hand, the differential inhibition was not obtained with the organophosphate inhibitors such as tetraethylpyrophosphonate (TEPP) or di*iso*-propylfluorophosphonate (DFP). They concluded that the esteratic site on the enzyme, where the latter inhibitors are believed to act, was probably the same in the two enzymes, while the anionic site where the positive charged quaternary ammonium inhibitors are thought to be attached is probably different.

We have now found, however, that differential inhibition of the enzymes present in the three phenotypes can also be obtained using sodium fluoride as inhibitor. Furthermore, the use of this inhibitor has enabled us to demonstrate the occurrence of at least two new phenotypes.

Sera from a series of individuals already classified by dibucaine number determinations were examined using fluoride as inhibitor. Inhibition with fluoride and determination of the so-called fluoride number (F.N.) were carried out in exactly the same way as dibucaine number determination except that 5×10^{-5} *M* fluoride was substituted for 10^{-5} *M* dibucaine in the test system. In all, sera from 179 individuals with the 'usual' phenotype, 84 individuals with the 'intermediate' phenotype, and 22 individuals with the 'atypical' phenotype were examined.

Fig. 1 shows the distribution of the fluoride numbers for the three classes. The means and standard deviations are given in Table 1. The F.N. obtained for the 'atypical' phenotype as defined by the D.N. determination are much lower than those for the 'usual' phenotype, and the phenotype 'intermediate' by D.N. determination is also intermediate in F.N. The discrimination between the three phenotypes using fluoride is nearly as clear cut as with dibucaine, and it is apparent that with few exceptions the classification of individuals obtained with fluoride is much the same as that obtained with dibucaine.

Table 1

Phenotype	No. of individuals	'Dibucaine number'		'Fluoride number'	
		Mean	Standard deviation	Mean	Standard deviation
'Usual'	179	80·06	1·56	61·35	3·21
'Intermediate'	84	61·93	4·17	47·79	4·48
'Atypical'	22	21·82	2·92	23·14	2·23

Table 2

Parental types	No. of families	Children			
		U	U_1	I	I_1
$U \times I$	20	36	—	32	—
$U \times I_1$	2	—	5	5	—

The exceptions, however, turn out to be of special interest. A plot of dibucaine number against fluoride number in the 285 individuals examined (Fig. 2) revealed that there was apparently a small sub-group of the 'intermediate' phenotype (D.N. 52–54, F.N. 26–34) in which the fluoride inhibition was relatively less marked than the dibucaine inhibition, and that a similar sub-group of the 'usual' phenotype also existed (D.N. 73–78, F.N. 50–55). The reality of these sub-groups has been confirmed by family studies. Thus, if we call the main groups of the 'usual' and 'intermediate' phenotypes U and I respectively, and the corresponding sub-groups U_1 and I_1, we have been able to compare the offspring from a series of matings $U \times I$ with those from $U \times I_1$ matings. The results are given in Table 2, and they indicate that U_1 and I_1 are genetically related.

These findings, and those from other types of mating, suggest that there may be a third gene which can influence the character of the cholinesterase

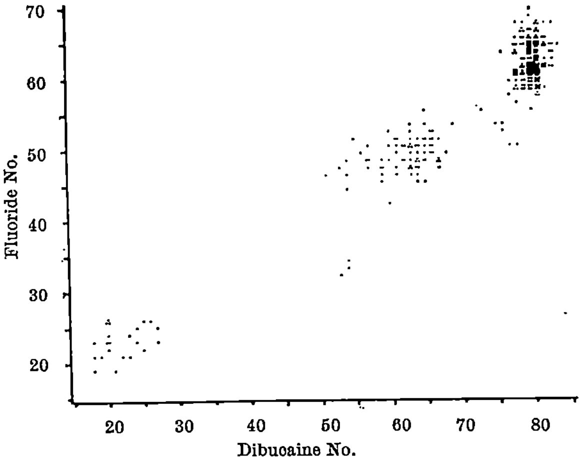

Fig. 2. Correlation between dibucaine numbers and fluoride numbers in the individuals shown in Fig. 1

synthesized. If so, the phenotype sub-groups, U_1 and I_1, would be determined by the presence of this gene in heterozygous combination, with the normal and abnormal genes previously identified. Possibly, this new gene determines yet a further variant of the enzyme which is qualitatively distinct, but much more work is required before this hypothesis can be substantiated.

We wish to thank Dr. H. Lehmann for many of the serum samples. We also wish to acknowledge a grant from the Central Research Fund of the University of London for the purchase of a spectrophotometer.

The First Anthocyanins appearing during the Ripening of Blueberries

Although a great deal is known of the anthocyanins of berries and other fruit, this knowledge is still quite superficial and fragmentary[1]. How and in what order the anthocyanins develop in the maturing berries has only been clarified in one case: the first anthocyanin compound to appear in Californian 'Cabernet' grapes was found to be the malvidin-3,5-diglucoside; with advanced ripening of the grapes, malvidin-3-glucoside and delphinidin-3,5-diglucoside develop at almost the same time, while petunidin-3,5-diglucoside is the last to be formed[2]. Free malvidin was not observed in the grape skins until one week after the berries had developed the purple-red colour of complete maturity. These observations are noteworthy because they show that anthocyanins and not anthocyanidins are the first to appear during maturation. Furthermore, the first anthocyanin formed, malvidin-3,5-diglucoside, has quite a complicated structure. This anthocyanin is considered to be the dominant pigment in these grapes.

In order to gain further insight into the development of anthocyanins in maturing fruit, we decided to investigate the blueberry, *Vaccinium myrtillus* L., the characteristic berry of the northern forests of Europe. It is known that the ripe blueberry contains at least seven anthocyanins, derivatives of delphinidin, malvidin, petunidin and cyanidin[1]. Collecting the pigment from raw, reddish berries in sufficient amounts for identification was found to be too laborious a task. The pigments separated from raw berries were therefore compared with pigment fractions from ripe blueberries, which thereafter were used for the purpose of identification.

The pigments were extracted from the skins of raw, reddish blueberries with methanol containing 1 per cent hydrochloric acid. Two anthocyanins were found by paper chromatographic analysis of the methanolic extract (*n*-butanol/acetic acid/water, 4 : 1 : 5), one in amounts twice as large as the other. After acid hydrolysis and paper chromatographic analysis with 'Forestal' solution both these anthocyanins were identified as cyanidin derivatives. Free anthocyanidins were not found in the raw berries. Both anthocyanins were later examined by paper chromatography, with *n*-butanol/acetic acid/water (4 : 1 : 5), water/acetic acid/hydrochloric acid (82 : 15 : 3) and *n*-butanol/2 *N* hydrochloric acid (1 : 1) as solvent systems. The less-abundant compound was found to be identical with the third fraction, the more abundant pigment being identical with the fourth fraction obtained by column chromatography from ripe blueberries (Fig. 1).

The anthocyanins were extracted from the skins of ripe blueberries with the acidified methanol, precipitated as lead salts, dried, and again treated with the above solvent. From the regenerated solution a crude preparation of the pigment was obtained by addition of ether[2,3]. About 200 mgm. of the preparation was examined chromatographically

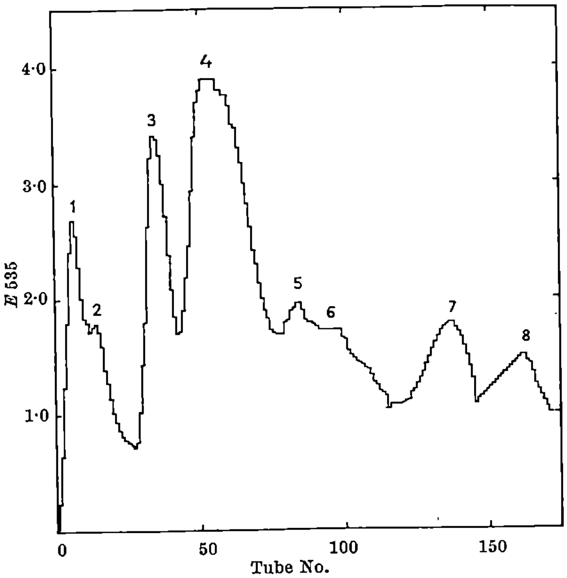

Fig. 1. Fractionation of the anthocyanins of the blueberry (*Vaccinium myrtillus* L.) using a cellulose column filled with Whatman cellulose powder and *n*-butanol/2 *N* hydrochloric acid (1 : 1) as developing solvent

in a column (5 cm. × 110 cm.) filled with cellulose powder (Whatman cellulose powder, standard grade or 'Linterspulver' No. 124, Schleicher and Schüll), *n*-butanol/2 *N* hydrochloric acid (1 : 1) being used as the solvent system[4]. The eluate was collected in 10-ml. fractions and the colour was measured at 535 mμ. From a graph with plots of extinction values (Fig. 1), it was found that the anthocyanins of the blueberry separate out into 8 peaks.

Samples of the eluates of peaks 3 and 4, which correspond to the anthocyanins of reddish blueberries, were hydrolysed by heating. The R_F values obtained by paper chromatography of the liberated anthocyanidins are shown in Table 1. The results establish that the aglycones of both anthocyanin fractions can be identified as cyanidin. This was confirmed by the distribution and oxidation tests and tests with the cyanidin reagent, sodium acetate and ferric chloride (Robinson's method).

The sugars were determined from the hydrolysed fractions 3 and 4. The water extracts were concentrated to about 10 ml., the hydrochloric acid was eliminated by extracting with 10 per cent di-*n*-octylmethylamine containing chloroform, and the solution was further concentrated to 1 ml. The sugars were identified by paper chromatography (*n*-butanol/acetic acid/water, 4 : 1 : 5), and it was observed that fraction 3 contained glucose and arabinose, fraction 4 glucose only. Control experiments proved that the arabinose was not an artefact produced either from the Whatman cellulose powder or from the paper (see ref. 5). Aniline–citric acid reagent was used in the quantitative determinations of the sugars. Comparison of the separately determined concentrations of the aglycones with the sugar concentrations proved that the concentration of glucose in both fractions was in almost equimolar proportion to the concentration of the anthocyanidin. The amount of arabinose, however, was found to be only half the equivalent amount, possibly owing to disintegration or partial splitting.

Table 2 shows the values obtained by paper chromatographic analysis of the anthocyanins. The R_F values of the anthocyanin in fraction 4, the largest fraction, in different solvent systems was found to correspond to the R_F values of cyanidin-3-glucoside. Considering the equivalent proportions of the aglycone and the sugar, the anthocyanin must be cyanidin-3-glucoside. In fraction 3 the R_F values of the arabinose-containing cyanidin derivative do not—as expected—agree with the R_F values of the reference preparations. According to the literature, however, the R_F values of this fraction closely approach the migration of cyanidin-3-glucopentosides.

In conclusion, the two anthocyanins initially appearing during the maturation process of blueberries are both found to be cyanidin derivatives. These two cyanidin derivatives, the first to appear being cyanidin-3-glucoside, and the arabinose-containing cyanidin derivative (possibly cyanidin arabinoglucoside), are the most abundant pigments of ripe blueberries, although it is known that the ripe berries also contain glycosides of malvidin, delphinidin and petunidin[1]. The order of appearance of these pigments during the ripening process bears out the earlier concept of Robinson[6] that biogenetically cyanidin should be regarded as the simplest of the anthocyanidins.

We thank Dr. C. G. Nordström for the preparation of cyanidin-3,5-diglucoside which he kindly placed at our disposal.

PHYSIOLOGY

Effect of Administration of Lysergic Acid Diethylamide on Serotonin-Levels in the Body

In a previous publication[1], we have suggested that some of the effects of lysergic acid diethylamide (LSD) may be mediated through its effect on the serotonin content of brain. Brodie and his associates[2] have previously reported that LSD—and also some other drugs—do not release serotonin as reserpine does. However, Freedman[3] has recently reported slightly raised levels of serotonin in the whole brain of rats treated with LSD. Using animals which had been given reserpine, they found a twofold increase of brain serotonin in rats treated with LSD over the controls receiving reserpine alone. The whole brain serotonin may not be a true indication of the action of a psychopharmacological agent. Thus Vogt and her associates[4] have reported different effects of LSD and serotonin in different areas of the brain after intraventricular injection.

We have investigated the effect of LSD on the serotonin content of the different parts of the rabbit brain. The brain was divided into four major parts : (1) cerebral hemispheres, excluding midbrain, pons, thalamus, hypothalamus, etc., and mostly consisting of the grey and white matter; (2) cerebellum; (3) stem; and (4) rest of the brain.

The animals were given intravenously 500 µgm. of LSD and were killed 15 min. later. In a second series of investigations, the rabbits were given intravenously 0·92 mgm., equal to 10 µc., of 5-hydroxytryptophan-3-^{14}C (5-HTP) followed by 500 µgm. of LSD 45 min. later. The experimental animals were killed 15 min. after the administration of LSD, while the controls received no LSD and were killed 1 hr. after the administration of the 5-HTP. Since the nature of the results as to the effect of LSD on the serotonin content was similar in both series of investigations, the results of the second series only are reported here. Table 1 presents the results as an average of four to six animals for each group. The first column represents the amount of total radioactivity per gm. of tissue and consists of the radioactivity due to 5-HTP, serotonin and their metabolites. The second column presents the content of serotonin determined spectrophotofluorimetrically, while the third one shows the specific radioactivity of the serotonin. The experimental details will be presented in detail elsewhere.

Table 1. EFFECT OF ADMINISTRATION OF LYSERGIC ACID DIETHYLAMIDE ON THE LEVELS OF SEROTONIN IN THE BODY

Tissue	Total radioactivity (counts per min. per gm. tissue)		Serotonin (µgm. per gm. tissue)		Specific radioactivity of serotonin (counts/min./µgm.)	
	Control	LSD	Control	LSD	Control	LSD
Liver	884	665	1·74	2·62	14·3	15·0
Lung	545	439	1·02	1·46	7·0	3·0
Kidney	1,992	3,089	1·04	1·78	17·0	25·0
Spleen	1,753	1,713	42·14	55·14	1·8	2·3
Heart	277	346	1·34	3·86	—	3·3
Cerebrum	76	83	0·96	0·90	1·2	5·7
Cerebellum	112	450	1·24	1·72	0·7	2·1
Stem	108	273	2·12	2·94	—	6·8
Rest of brain	132	469	2·08	2·68	1·4	4·6

The effect of the administration of small quantities of 5-HTP was a small rise in the serotonin content of the tissues. The spleen is an extremely rich source of serotonin. Several interesting facets of serotonin metabolism are revealed by this work. The specific radioactivity of the serotonin is an index of the metabolic rate of serotonin in the tissue. Thus, kidney and liver are the most active sites, while the serotonin of the spleen is not in such an active state. It could be seen that the total radioactivity of the kidney is enhanced very much subsequent to the administration of LSD. This suggests that a considerably larger amount of the 5-HTP is transported to the kidney in the animal treated with LSD. The increase in the specific activity of serotonin is highest in the kidney, while on a percentage basis it is next highest to the brain tissues. This indicates an increased turnover of serotonin in the kidney and also a general increase in the serotonin content of the different parts of the viscera.

In the cerebrum there is no increase in the serotonin content in the animal treated with LSD. This is presumably due to the rapid destruction of the serotonin by oxidation, as is indicated by the higher specific activity of the serotonin. In other parts of the brain also, whereas the serotonin content increases only by approximately 40 per cent, the specific activity increases by about 350 per cent.

Thus these results indicate an overall increased metabolism of serotonin and an increase of the content of serotonin itself in all parts of the body examined, except in the cerebrum, subsequent to the administration of LSD. Whether the effects of LSD are specific or are shown by its non-hallucinogenic analogue, bromo lysergic acid diethylamide, and whether the action of LSD is limited to serotonin only without significant effects on other neurohormones such as noradrenaline is being investigated.

Effect of the Bilateral Section of the Splanchnic Nerve on Erythropoiesis

DESPITE much recent work on erythropoietin which has established the important part played by the humoral factor in erythropoiesis, participation of the nervous system in the regulation of erythropoiesis has not been established. In view of the report of Jacobson *et al.*[1] suggesting the renal production of erythropoietin, as well as the work of Nakayama[2] that showed the effect of the bilateral section of splanchnic nerve in abolishing the decrease of renal blood-flow on loss of blood or anoxic anoxia, we performed a bilateral section of splanchnic nerve in rats to observe the effect on erythropoiesis.

The splanchnic nerve was sectioned bilaterally in the Wistar female rats (180–200 gm.) through the

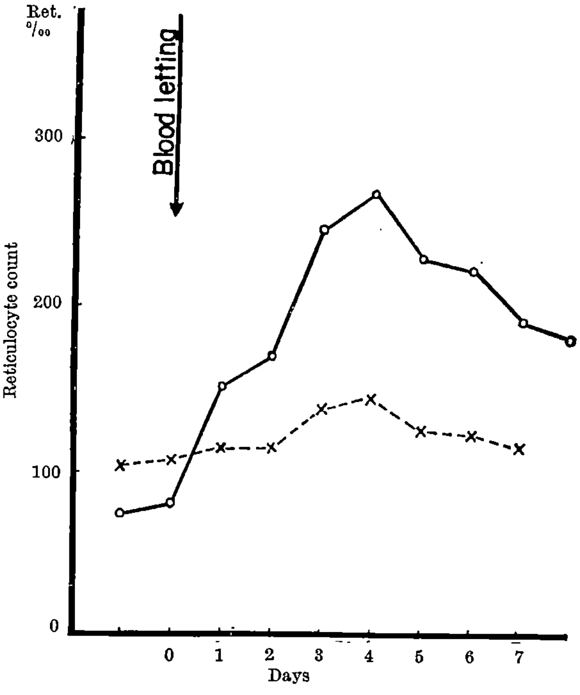

Fig. 1. Effect of bilateral section of splanchnic nerve on reticulocytosis after blood-letting (30 per cent of total blood volume). Each point represents the mean value for five rats. o, normal; ×, operated

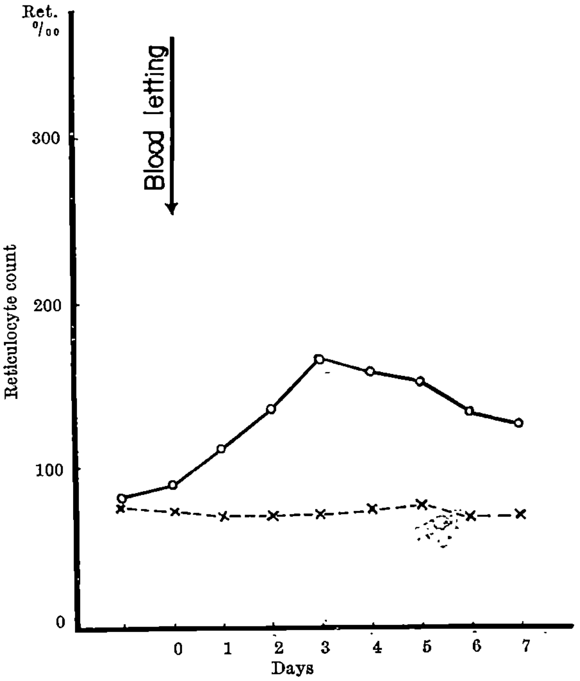

Fig. 2. Effect of bilateral section of splanchnic nerve on reticulocytosis after blood-letting (20 per cent of total blood volume). Each point represents the mean value of five rats. o, normal; ×, operated

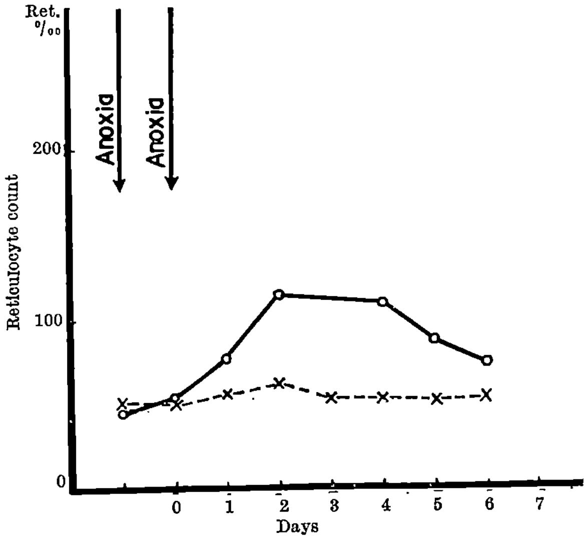

Fig. 3. Effect of bilateral section of splanchnic nerve on reticulocytosis after anoxic anoxia. Each point represents the mean value of five rats. o, normal; ×, operated

abdominal approach. After being bled as much as 1·0–1·5 per cent of their body-weight representing a loss of 20–30 per cent of the total blood volume[3] by cardiac puncture, the changes in the reticulocyte counts were followed in normal and operated rats. The results of experiments in Figs. 1 and 2 show that the loss of 30 per cent and 20 per cent of their total blood volume caused only a slight or no increase in reticulocytes in rats with a sectioned splanchnic nerve in contrast to the marked response to the same procedures for normal rats. When subjected to a mild anoxic anoxia, the rats with a sectioned splanchnic nerve showed no increase in their reticulocyte counts (Fig. 3). Such loss of the reticulocytic response in rats with sectioned splanchnic nerve suggests that the reduction of renal blood-flow which is regulated through the splanchnic nerve plays an important part in the production of erythropoietin when there is loss of blood or anoxic anoxia.

The reduction of the flow of arterial blood to the abdominal organs, including the kidney, in case of loss of blood has been explained as a mechanism for protecting the brain or heart from anoxia. By the experiments performed in our laboratory, it is suggested that the reduction of flow of arterial blood through the kidney in case of loss of blood occurs not only to protect the brain or heart but also to stimulate the erythropoietin production to facilitate the recovery from anæmia.

Dependence on Substrate of the Electrical Potential across the Isolated Gut

PUBLISHED reports[1,2] have indicated that fluid and salt transport across the isolated small intestine is very low in the absence of an external supply of substrate. Chemical measurements of net transport have shown that, of the many substrates tested, only glucose is able to support optimal absorption[1]. With such measurements, the tissue must be allowed to equilibrate for 20–30 min. before sufficient fluid or salt has been transported to allow accurate chemical measurements. Thus a considerable uncertainty exists as to how rapidly the absorptive process changes when glucose is added to or removed from the bathing media. A clarification of this point would indicate the extent to which utilizable energy is stored in the tissue.

By use of electrical techniques, rapid changes in salt absorption across the epithelia can be followed[3]. In this investigation, it was decided to monitor changes in the electrical potential difference established across the tissue as a consequence of the active absorption of sodium chloride[4,5]. Electrical potentials across isolated segments of rat small intestine (Rochester strain of Wistar) were measured by a technique described before[5], in which the small intestine could be transferred rapidly (within 3 sec.) from one solution bathing the mucosal side to another. Since the potential was found to be unaffected by the glucose concentration of the serosal solution, only the results of glucose changes in the mucosal solution will be presented.

Fig. 1 records the effects of glucose on the potential developed across the mid-jejunal segments. When the tissue was exposed to 200 mgm. per cent glucose in the presence of oxygen/carbon dioxide, the potential was maintained for at least 60 min. However, when the segment was transferred to a glucose-free medium a 60 per cent drop in potential occurred in 2 min. On returning to glucose medium, the potential was restored within 3–5 sec. These data clearly indicate that there is very little utilizable stored energy.

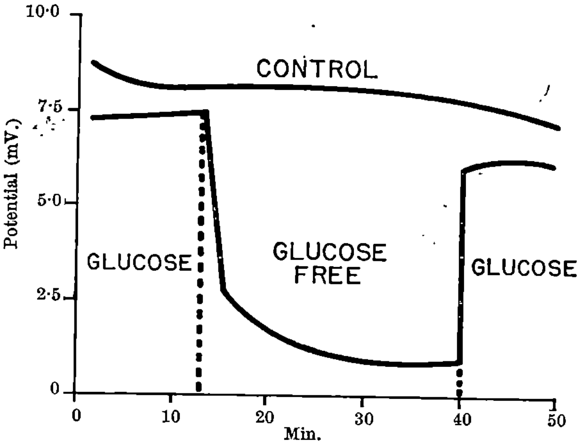

Fig. 1. Effect of glucose on the electrical potential across isolated segments of rat small intestine. Everted mid-jejunal segments were exposed to Krebs–Ringer bicarbonate buffer containing 200 mgm. per cent glucose and to a similar buffer containing no glucose at 37° C. in the presence of 95 per cent oxygen/5 per cent carbon dioxide. Ileal segments behaved identically except that their potentials were, on the average, 50 per cent less. The positive recording electrode was in contact with the serosal solution

The rapid recovery of the potential on addition of glucose deserves further comment. Chinard *et al.*[6] have reported that the mean transit time for passage of glucose across the mucosal cell of the proximal tubules of the kidney is 10 ± 3 sec. Since both cells have a similar structure and are able to transport glucose actively, one would conclude that the mean time of entry for glucose moving into the intestinal cell is about 5 sec., corresponding to the recovery time of the potential as noted in Fig. 1. Thus it is seen that the active transport of salt is stimulated immediately on the entry of glucose into the mucosal cell.

Investigations on the relationship of energy metabolism to active transport have been reported for frog skin[7] and toad bladder[8]. These epithelia have sufficient endogenous substrate to support active transport for many hours. On the other hand, the intestine, because of its complete dependence on external substrate, allows the person performing experiments a greater degree of control of the energy supply. For this reason the isolated small intestine presents an excellent preparation for the study of transfer of energy within the cell.

This investigation was carried out under contract with the United States Atomic Energy at the University of Rochester Atomic Energy Project, Rochester, New York.

Soluble Material in the Gastrointestinal Tract of Rats under Normal Feeding Conditions

Work on intestinal absorption has almost always been carried out under non-physiological conditions—on fasted animals fed by stomach tube, on anæsthetized animals or animals with fistulæ and on isolated loops. Moreover, single nutrients have usually been administered. It seemed desirable to obtain information under more nearly physiological conditions and to examine the medium from which absorption was proceeding at different levels of the gastrointestinal tract.

Adult male rats were kept in an automatically lighted room arranged so that the period of darkness during which they do most of their feeding was 5 a.m.–2 p.m. They were provided with Thomson cube diet containing 14 per cent dried milk and water *ad libitum*. The animals were killed between 9·0 and 10·0 a.m. and immediately taken to a cold room (4° C.) where the stomach and small intestine were removed. The stomach (S) was tied off and the intestine divided into four arbitrary segments of approximately equal length labelled I_1–I_4, beginning at the pylorus. The contents of the stomach and intestinal segments were removed and spun in a refrigerated centrifuge at 4,000 r.p.m. for 20 min. This usually gave 0·05–0·5 ml. fluid for analysis.

In all animals the stomach contained 3–5 ml. of thick pasty material while the most proximal intestinal segment (I_1) was almost empty, containing only a small amount of thick mucous fluid with few insoluble food residues. The other intestinal segments (I_2–I_4) contained large amounts of material looking like homogenized rat cubes.

As shown in Table 1, there was a large reduction in the concentration of potassium between (S) and (I_2), the concentration in I_3 and I_4 remaining steady. The fall in the concentration of sodium was less pronounced. Chloride estimations were carried out by the Conway micro-diffusion method but the results were not included in the table since they varied widely from animal to animal. But while concentrations of more than 200 m.equiv./l. were sometimes found in the stomach the values for I_3 and I_4 never exceeded 10 m.equiv./l. The nature of the anions present in the lower half of the small intestine, where the concentration of $Na^+ + K^+$ amounted to 80–100 m.equiv./l., is not clear. Bicarbonate may have been present but was not estimated; yet supposing it was present at a level similar to that of plasma, that is, 27 m.equiv./l., this would leave more than 40 m.equiv./l. anions not accounted for. Some of the base may have been bound by the products of protein digestion since the amino nitrogen present in I_3 and I_4 was about 1 gm./l. or 70 m.equiv./l.

The concentration of total nitrogen in the centrifugates was highest in I_1, exceeding that in the stomach, and it fell progressively in the lower segments. The bulk of the nitrogen-containing material was not precipitable by sodium tungstate, that is, was non-protein nitrogen. The pattern for total nitrogen concentration was roughly paralleled by the non-protein levels.

Reducing and total sugar concentrations are expressed as glucose. There was a marked fall in the concentration of free and total reducing sugar between S and I_1 and this did not appear to be due to simple dilution since in all cases only small quantities of material were present in I_1, reflecting the rapid

Table 1. CONCENTRATION OF VARIOUS CONSTITUENTS OF THE SOLUBLE MATERIAL PRESENT AT DIFFERENT LEVELS OF THE GASTRO-INTESTINAL TRACT OF RATS UNDER NORMAL FEEDING CONDITIONS

Segment	S	I_1	I_2	I_3	I_4
Potassium (m.equiv./l.)	135 (± 9·3)	51·5 (± 6·6)	29·0 (± 3·0)	18·5 (± 3·5)	18·6 (± 1·9)
Sodium (m.equiv./l.)	136·6 (± 9·9)	109·4 (± 14)	85·1 (± 18)	80·1 (± 8·7)	68·3 (± 10·0)
Total nitrogen (gm./l.)	6·6 (± 1·0)	9·1 (± 3·1)	6·3 (± 1·3)	4·77 (± 0·45)	3·85 (± 0·26)
Non-protein nitrogen (gm./l.)	4·16 (± 1·3)	6·56 (± 3·1)	5·8 (± 1·5)	4·02 (± 0·6)	3·44 (± 0·28)
Free reducing sugar (as gm. glucose/l.)	68·4 (± 5·8)	10·9 (± 3·6)	21·2 (± 3·8)	21·5 (± 2·9)	20·8 (± 4·1)
Total reducing sugar (as gm. glucose/l.)	93·4 (± 15·4)*	See footnote †	29·3 (± 5·6)*	33·6 (± 4·7)*	35·1 (± 6·2)*

Figures in brackets show the standard deviation for five observations except where indicated by *, when only four observations were made.
† Three observations only. In these, the increase in reducing power on hydrolysis was 1·61 (± 0·29) gm./l.

passage of food through the upper part of the small intestine. The slight difference between the free and total reducing sugar in this segment suggested that monosaccharides constituted the major carbohydrate fraction.

The free reducing sugar was remarkably constant between segments I_2, I_3 and I_4, where it was present at a concentration of about 2 per cent. This constancy was unexpected since it is generally believed that all digestible carbohydrate is absorbed before the chyme leaves the small intestine, and some decrease in reducing power in the last segment might therefore have been expected. The results are of interest in view of Fisher's[1] finding that absorption of water only proceeds from the isolated small intestine of the rat when glucose is present in the lumen.

It is emphasized that these are preliminary results with a small number of animals (5) and that certain improvements of technique are considered to be necessary, for example, a different method of killing instead of the ether anæsthesia and bleeding used here; nevertheless the results are sufficiently consistent to suggest that this more physiological approach to the study of gastro-intestinal function may be of value.

HÆMATOLOGY

Stability of Freeze-dried Anti-hæmophilic Globulin

THE stability of anti-hæmophilic globulin in solution has been the subject of many investigations. Hitherto, no systematic work on the factors affecting the activity of dried material has been reported.

In order to obtain comparable results in the present investigation, the period necessary for the loss of 50 per cent of the activity of anti-hæmophilic globulin[1], subjected to the necessary conditions of each experiment, was estimated. Bovine, porcine and human anti-hæmophilic globulins were utilized; no appreciable difference was observed in their behaviour.

Type of container: Anti-hæmophilic globulin stored at room temperature in stoppered M.R.C. bottles or universal containers lost half the activity in two months. Storage in darkness had no significant effect. On the other hand, sealed ampoules preserved the same activity for four months.

Effect of temperature: Sealed ampoules were used in this test. Deterioration was rapid at 37° C.; the standard loss occurred after 5–8 days. At 4° C. the same loss was observed after storage for six months.

Storage under vacuum over phosphorus pentoxide: This had practically the same effect as that produced by storage in sealed ampoules.

Humidity: When samples of anti-hæmophilic globulin in loosely stoppered universal bottles were kept in a humid atmosphere, two weeks were sufficient to lower the activity to 50 per cent.

Time of packing: The potencies indicated on commercial ampoules were invariably found to be higher than my estimates. This led to inquiries which showed that in certain cases this was most probably due to a time-lag between the completion of the drying process (when the activity was determined) and packing. When this delay was minimized, not only did our figures coincide but also the preservation of the activity was prolonged; the subsequent loss of activity of samples treated in this way was almost halved.

It would now appear that in order to obtain and preserve the maximal activity of anti-hæmophilic globulin, delay should be avoided in drying and sealing the material in evacuated or nitrogen-filled ampoules, which should be stored at 4° C.

This work was supported by a grant from the United Manchester Hospitals. I thank Dr. J. F. Wilkinson for laboratory facilities.

New *Rh* Phenotype, $Dcce^ie^if$, found in a Chibcha Indian Tribe

IN the course of serological work on various Chibcha-Indian tribes of Colombia it was found that the blood of 6 out of 113 Ica Indians, inhabitants of the Sierra Nevada of Santa Marta, reacted with anti-*D* and anti-*c* sera but failed to react with anti-*C*, anti-*E*, and anti-*e* sera. Further laboratory work carried out at the Caracas Blood Bank as well as in the Blood Group Research Unit of the Lister Institute of London and at the Mount Sinai Hospital in New York has demonstrated that the six samples previously mentioned reacted with anti-*f* and with some anti-*e* sera as well.

Considering these results, we may call the new phenotype $Dcce^ie^if$ and the chromosome $Dce^if(R_i)$, using the *i* as indicative of the tribal denomination of the Ica among whom the phenotype was found for the first time. Genetic studies of a family carrying this chromosome, together with the serological evidence for the differentiation of this phenotype from other *Rh* gene complexes like *Dc-* (ref. 1), will be published elsewhere (Layrisse, M., Layrisse, Z., and Wilbert, J.).

Table 1 shows the frequencies of the *Rh* phenotypes and chromosomes found in 113 samples. For the calculation of the chromosomes we assumed that the phenotype *Dcce* is the expression of dce/Dce^i, since the chromosome *Dce* is rare in pure Indians and since no Negro genes were found in this population: *Js*(*a*–), hæmoglobins *S* and *C* were negative, and the gene *B* (0·44 per cent) was lower than A_1 (1·34 per cent).

Table 1. *Rh* FREQUENCY IN ICA TRIBE USING ANTI-*D*, ANTI-*C*, ANTI-*c*, ANTI-*E* AND ANTI-*e*

Phenotypes	Genotypes	No. observed	Frequency observed	Frequency expected	χ^2 $\left(\frac{\text{Obs.}-\text{exp.}}{\text{Exp.}}\right)^2$
DCCEE	*DCE/DCE*	0·00	0·00	0·00	—
DCCEe	*DCE/DCe*	0·00	0·00	0·00	—
DCCee	*DCe/DCe*	46·00	40·71	36·75	0·43
DCcE	DCE/Dce^i *DCE/DcE*	0·00	0·00	0·00	—
DCcEe	*DCe/DcE*	10·00	8·85	13·39	1·53

DccE	*DcE/DcE* DcE/Dce^i	5·00	4·42	5·66	0·25
DccEe	*DcE/Dce*	5·00	4·42	1·81	
Dcce	dce/Dce^i	5·00	4·42	3·31	0·44
ddccee	*dce/dce*	1·00	0·89	0·68	
$Dcce^ie^i$	Dce^i/Dce^i	6·00	5·31	4·04	0·40
Total		113·00	99·99	99·99	3·38 $0{\cdot}70 > P > 0{\cdot}50^{n=5}$

Chromosomes (per cent)	
DCe	60·62
DcE	11·05
dce	8·22
Dce^i	20·11

The peculiar distribution of the chromosome Dce^if among the Chibcha tribes studied is rather surprising. Whereas it occurs in a relatively high frequency among the Ica (20 per cent), the phenotype which identified this chromosome was absent in the two other tribes (Tunebo and Paez) of the same linguistic affiliation (Layrisse, M., Layrisse, Z., and Wilbert, J.).

Since not more than 10 South American Indian tribes have been tested with both anti-*E* and anti-*e*, we shall have to wait for further results before any statement concerning the frequency of the new chromosome in the autochthonous population of the New World can be advanced.

We thank Drs. R. Sanger and R. R. Race for assisting in the study of the family carrying the chromosome; Dr. R. E. Rosenfeld, who provided anti-*f* serum and tested one case of the phenotype $Dcce^if$ shown in Table 1, and Dr. Levine, who provided another serum used in this work. The Creole Foundation, Caracas, sponsored the project and the Instituto Colombiano de Antropología rendered most useful assistance.

HISTOCHEMISTRY

Direct Relationship of Phosphorylase and Mitochondrial α-Glycerophosphate Dehydrogenase Activity in Skeletal Muscle

PREVIOUS work[1] showed that in mammalian and avian muscle fibres there was a reciprocal relationship between phosphorylase and the oxidative enzymes, as shown by histochemical techniques. Two groups of fibres were described. In the histologically larger group, there was high phosphorylase activity and low activity of oxidative enzymes. (These included succinate, lactate, malate, isocitrate, β-hydroxybutyrate, alcohol and glutamate dehydrogenases, and also the DPN-linked α-glycerophosphate dehydrogenase.) In the group of histologically smaller fibres the converse activities were present.

With the development of a histochemical technique capable of demonstrating the purely mitochondrial α-glycerophosphate dehydrogenase[2], which is not linked with coenzyme, its localization in muscle has become possible. The enzyme is found to be strongly concentrated in the group of larger fibres. Activity in the smaller fibres is weak or absent. Mitochondrial α-glycerophosphate dehydrogenase activity thus runs parallel with phosphorylase activity, unlike all other oxidative enzyme systems so far tested.

Since the non-mitochondrial α-glycerophosphate dehydrogenase is strongest in the group of smaller fibres, the present findings do not fully support the concept that an α-glycerophosphate cycle[3] is an important metabolic pathway in the larger fibres. They do, however, fit the supposition that dihydroxyacetone phosphate, produced by α-glycerophosphate dehydrogenase activity, could enter the Embden–Meyerhof pathway at the level of triosephosphate isomerase. They provide further support for the thesis that the two types of muscle fibre rely substantially on different metabolic pathways in obtaining their supplies of energy for muscular contraction.

HISTOLOGY

Deoxyribonucleic Acid Content of Nuclei dividing amitotically

THE presence of a rather high percentage of binucleated cells in the rat epididymis, especially in the body and tail, is well known[1–3]. The two nuclei, which are approximately equal in volume, arise by amitotic division, as judged by the complete series of morphological stages which can be traced from a small radial fold in the nucleus to its complete subdivision by a furrow. The nuclei remain in close contact with one another, usually with their apposed surfaces flattened.

It is now known that cells about to divide mitotically have twice the deoxyribonucleic acid (DNA) content of resting, undividing cells and that binucleate cells, at least in the liver, have twice the normal diploid amount of DNA[4-6]. It seemed of interest to determine whether the same phenomena would be observed in cells dividing amitotically.

Small portions of the neck of the rat epididymis were dissociated by trypsin digestion and squashed in isotonic sucrose. Fixation for 15 min. in formalin vapour was followed by extraction of plasmalogenic lipids in alcohol and boiling alcohol-ether. After rehydration the slides were stained by the Feulgen procedure. The nuclei were homogeneous and well suited to photometry.

The optical density of the nuclei of mononucleate and binucleate cells was determined in a modified Lison-type histophotometer. With the densities encountered glare could be completely neglected. The projected area of each nucleus was sampled representatively (10 readings) and the resulting mean density multiplied by the area (planimetrically determined) to give DNA content in arbitrary units. Since there was some variation in the measured mean DNA contents in the five specimens of epididymis examined, the values were recalculated to a common mean on the basis of the DNA content of the mononucleate cells. These always formed a single population of nuclei as judged by inspection of the frequency histograms.

Histograms showing the DNA contents of both mononucleate and binucleate cells are shown in Fig. 1. It will be seen that the nuclei of mononucleate cells form a single population. Inspection shows no evidence of any skewness of the frequency distribution, as might be expected if there were a doubling of DNA content before the amitosis.

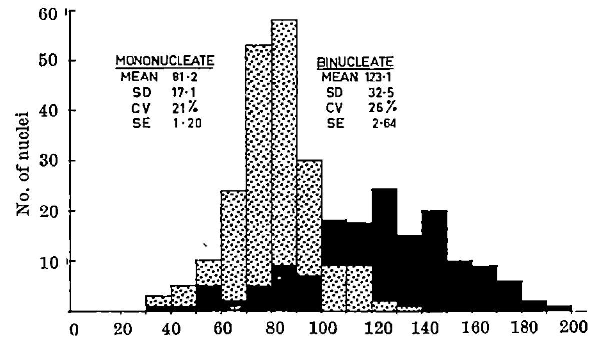

Fig. 1

The binucleate cells also form a single population of cells with respect to DNA content, the mean value being almost exactly half as much again as that of the mononucleate cells (123·1 ± 2·64 as against 81·2 ± 1·20).

It is clear that there is no doubling of the DNA content of the nuclei either before or after amitotis but that, when the amitosis has occurred, there is an increase in DNA content to a value which is 150 per cent of that of the mononucleate cells.

These results can be explained by the following theory: in a nucleus like a rat epididymal nucleus which is not subject to mitosis or endomitosis (endopolyploidy) the presence of two homologous chromosomes normally inhibits duplication of either one. When, however, the homologous chromosomes are separated from one another by the development of the nuclear partition which arises during amitotic division, the control mechanism no longer operates and each duplicates itself (polysomaty or polynemy).

When the chromosome number is large (as in the rat), and in the absence of any somatic pairing, the distribution of paired and unpaired chromosomes in the two nuclei arising by amitosis closely approximates a binomial distribution in which $p = q = 0 \cdot 5$ and $n = 21$ (the number of chromosome pairs). The mean value is 10·5 paired and 21 unpaired chromosomes. Duplication of these unpaired chromosomes would lead to an increase of 50 per cent in the DNA content of the two nuclei.

The total variability in the binucleate cells is the result of normal biological and experimental variation and of the variation in the number of paired chromosomes. The first source may be calculated from the variance found in mononucleate cells and the second calculated from the above binomial expression. On this basis the expected standard deviation of the DNA content of the binucleate cells is 32, which is very similar to the value actually obtained (32·5).

The work here described appears to conflict with that of Vendrely[7], who measured the DNA content of about 90 nuclei chosen randomly from serial sections of mouse epididymis. Normal values were found except for some intermediate between diploid and tetraploid levels; these were ascribed to the presence of mitotic activity in the epididymis. Vendrely does not say how many of the nuclei measured were double.

I am indebted to Prof. H. O. Lancaster for help with the statistics. The work has been supported by the National Health and Medical Research Council and the Normal Haire and Cancer Research Funds of the University of Sydney.

Photo-Sensitivity of Thiazine Leucobases

During the course of experiments designed to investigate the staining of nucleic acid in histological sections, I happened to gather together on one bench a number of solutions of basic dyes reduced to their colourless sulphite leucobase. These included methyl green, basic fuchsin and a series of thiazines, namely, thionin, azure *A*, *B* and *C*, and methylene blue (for a discussion of the structure of these thiazine dyes, see Baker[1]).

The basic fuchsin leucobase (Schiff reagent) was prepared according to the directions of de Tomasi[2]. The other leucobases were prepared by dissolving 8 gm. of sodium thiosulphate in 100 c.c. of a 0·1 per cent solution of the dye in question. Once solution was effected, 0·5 c.c. concentrated hydrochloric acid was added, and the mixture heated over a bunsen flame for 30 sec. The result was a decolorized solution with a grey, curdy precipitate, best left unfiltered, as it appeared to stabilize the solution.

An accidental shaft of sunlight from a point source produced an intriguing result. Each of the thiazine leucobases developed a blue spot in the solution in relation to the point source of sunlight. The blue spot disappeared a few seconds after the solution was shielded from light. The leucobases of methyl green and basic fuchsin showed no such phenomenon. Further examination showed it was not elicited by the light from an ordinary tungsten filament bulb, although the tungsten light source in my microscope, distinctly blue at top intensity, was effective. Daylight indoors had very little result, but daylight outside even with a cloudy sky produced the blue colour almost immediately.

Ultra-violet light seemed the most likely excitant, so the leucobase solutions were placed in front of a Wood's lamp (mercury discharge). Blue-green fluorescence was immediately observed, maximal in the case of methylene blue and the azures, moderate in the case of thionin, absent in methyl green and basic fuchsin leucobases. On subsequent examination, all the leucobases which had fluoresced were also showing photo-oxidation, as proved by the return of the original dye colour, and its subsequent disappearance in the dark.

It appears clear that leuco-thiazines show various effects when irradiated with ultra-violet and possibly visible blue light. Effects of this kind may be responsible for the reputation which these leucobases have for 'instability'. In fact, thiosulphate preparations of thiazines will remain stable for months if kept in a dark, well-stoppered bottle. Even in Coplin jars with loosely fitting lids, reduction will be maintained for almost two weeks, if care is taken to exclude light.

All the dyes described in this communication were supplied by 'Chroma' of West Germany.

PATHOLOGY

Effects of *Grewia populifolia* Extracts on the Development of Chick Embryos

In the course of screening work with various plant extracts for their carcinolytic activities, *Grewia populifolia* extract was found to have anti-tumour activities when injected in rats bearing rhabdomyosarcoma (Kundu *et al.*, unpublished work). It was decided to inject this extract into fertile eggs to study its effects on the organogeny of early chick embryos in a way similar to that of Jurand[1].

Four different concentrations, namely, 16×10^{-5}, 20×10^{-5}, 24×10^{-5} and 32×10^{-5} gm. per c.c., were used. For each concentration, individual eggs from different groups received 1 c.c. of the solution; the *p*H of these varied from 6 to 7. It was found difficult to inject 1 c.c. of the solution into the egg. To overcome this, 1 c.c. of albumen was taken out with a syringe and replaced by the same volume of normal saline solution containing the required concentration. The injection was made quite near the blastoderm through a small hole that was resealed and covered with 'Cellotape'.

Before the injection, each group was incubated at 38° C. for nearly 18 hr. After injection, this was kept at 25° C. overnight to allow the extract to mix with the albumen, and then re-incubated for periods of 24 hr. and 48 hr. respectively. The controls were treated similarly and they received 1 c.c. of normal saline after the removal of 1 c.c. of albumen.

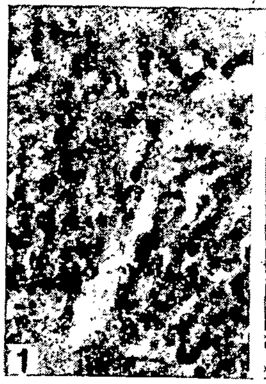
Fixation was carried out with acetic acid-alcohol. Sections were cut at 10μ thickness and stained with celestine blue. In some cases eosin was used as the counter stain.

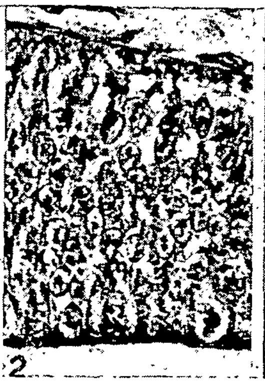
Of the four concentrations tested, 16×10^{-5}, 20×10^{-5} gm. per c.c. had no effect. This was revealed when the sections were examined under a microscope. A concentration of 32×10^{-5} gm. per c.c. appeared to be very toxic, as in all the eggs receiving this concentration the blastoderm at the time of inspection was disintegrated.

With 24×10^{-5} gm. per c.c. concentration, 60 per cent of the embryos were affected. The abnormalities observed were more or less similar in all the affected embryos. The most noticeable changes, observed after 48 hr. incubation, were the reductions in size of the embryo proper and the blastoderm. Examination of the sections revealed that the neural system was most severely affected throughout. The brain and the neural tube were enlarged, and their lumina were partially filled up with degenerated cell debris. In the brain particularly, the inner and the outer walls were broken, and the cells became loose with pycnotic nuclei (Fig. 1). Mitosis was rare. A section through the brain region from a control specimen clearly revealed the difference (Fig. 2).

In the neural tube, the outer wall was intact but the cell damage was similar to the brain tissue. The notochord revealed the same picture, but the sheath was intact. There was an increase in the mesenchymal cells and the dorsal aortæ were gorged with blood cells. The somites were affected only slightly in the posterior region of the embryo, and there was a clear differentiation into sclerotome, dermatome and myotome.

Examination of sections from embryos fixed after 24 hr. incubation showed that the neural tissue was enlarged. The inner wall of the brain and the neural tube were broken at places and cellular material





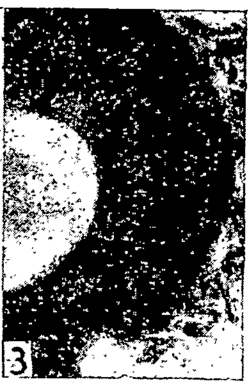


Fig. 1. Transverse section through the brain region of a treated embryo after 48 hr. of incubation. (× 200)

Fig. 2. Transverse section through the brain region of a control specimen after 48 hr. of incubation. (× 200)

Fig. 3. Transverse section through the brain region of a treated embryo after 24 hr. of incubation. (× 100)

was found scattered in the lumen, which appeared to have come from the cells lining it (Fig. 3). Mitosis could be observed, though less than the control. Other tissues which were observed to be affected after 48 hr. were more or less normal.

It appears from the present series of experiments that with concentrations of 24×10^{-5} gm. per c.c. of extracts of *G. populifolia* some organs of the developing embryos are affected. In the neural tissue there is an antero-posterior gradient in the degree of susceptibility, the brain being more affected than the neural tube, thereby showing that regions having a high rate of mitosis are more susceptible. This might also account for the lower degree of susceptibility of the somite where the rate of mitosis is not so great as in the two former tissues.

For the expansion of blastoderm tension is necessary, as reported by New[2]. This tension might have been reduced by breaking the intercellular connexions, resulting in a reduction of its size. A similar explanation has been given by Overton[3].

Engorgement of the blood vessels and an increase in the mesenchymal cells in the embryo proper might be due to the reasons suggested by Overton[3] and Waddington *et al.*[4].

The presence of mitosis after 24 hr. treatment and more or less its complete absence after 48 hr. with cellular derangement suggest that the extract of *G. populifolia* might have acted as a cytotoxic agent.

We are grateful to Dr. Subodh Mitra, director of this Centre, for his interest in the work, and to Dr. P. De for valuable discussions.

Pathological Parthenogenesis in a Viviparous Toothcarp

In viviparous toothcarps parthenogenesis has been described in *Lebistes reticulatus*[1,2] and *Xiphophorus helleri*[2], while in this species also some cases of development of ovarial teratomas, caused by pathological parthenogenesis, are known[3]. In addition to these cases we observed a new one, namely in *Heterandria formosa*. It concerns a female isolated immediately after birth and consequently free from any contact with the male sex. After reaching a length of 27 mm. the virginal animal dropped 4 young fishes, all female. After this the animal became pregnant twice again, resulting in the birth of 6 and 10 young fishes, respectively, also exclusively female. For microscopic confirmation of the virginity the ovarial sperm chambers were examined, no spermia being observed. This finding ruled out self-fertilization, a phenomenon incidentally found in viviparous Cyprinodonts and explained by the presence of a bisexual gonad producing oocytes as well as spermia. As in the cases already described[2,3], an infection process caused by the Phycomycete *Ichthyophonus hoferi* was present in the cranial part of the ovary and in the adjacent regions. If an extensive process had been localized in the caudal parts of the ovary and near the junction between ovary and oviduct, birth would undoubtedly have been prevented. The young females appeared without an exception to be haploid.

The coincidence of the *Ichthyophonus* infection on one hand and the parthenogenetic development on the other justifies the assumption that the pathological process in this case had caused the parthenogenetic development. It could be assumed that the *Ichthyophonus* toxin provided the artificial stimulus for the development of the unfertilized oocytes.

Summarizing, we may conclude that this case forms an argument for my theory of pathological parthenogenesis[2,3]. It would certainly be advisable in any new cases of parthenogenesis to carry out a systematic examination for the possible presence of a pathological process in the ovary or in the immediate surroundings of this organ.

Diagnostic Significance of Heterogeneous Lactic Dehydrogenases in Malignant Effusions

There is no laboratory test available for the differentiation of benign effusions from malignant exudates. Wroblewski and Wroblewski[1] reported in 1958 that, in malignancy, concentration of lactic dehydrogenase is frequently higher in effusions than in the corresponding sera. Nevertheless, the diagnostic value of these determinations is restricted since in about one-third of all cases investigated the amount of the lactic dehydrogenase in serum and effusion was the same[1]. Recent work on lactic dehydrogenase of tissues[2] and serum[3-5] indicates that this enzyme occurs in a number of molecular species which can be distinguished on account of their kinetics, antigenicity, inhibition by diphosphopyridine nucleotide analogues and electrophoretic mobility. In serum, starch block[3,4] and agar gel[5] electrophoresis and chromatography on diethylaminoethyl (*DEAE*) cellulose[6] showed the presence of at least four dehydrogenases, which are best labelled according to their electrophoretic mobility, namely, α_1, α_2, β and γ-lactic dehydrogenase. A specific increase in particular fractions has been observed in the following diseases: α_1 in myocardial infarction[3-6], $\alpha_1 + \alpha_2$ in muscular dystrophy[4] and γ in liver disease[5,6].

No information about the heterogeneity of lactic dehydrogenase in effusions is available. Since differences between malignant and benign effusions might occur, some thirty effusions were investigated by starch block electrophoretic separation[7] and determination of lactic dehydrogenase of each fraction using the optical test[8]. Effusions were centrifuged and the sediment discarded. 0·2 ml. serum or effusion was separated on starch block electrophoresis into four main fractions: α_1, α_2, β and γ. Lactic

Table 1. Lactic Dehydrogenase Iso-enzymes in Effusions (Starch Block Electrophoresis)

H-81	67	M	Cardiac failure						13·1	5·5	2·4	2·9	2·4
H-84	65	M	Cardiac failure						5·4	1·1	0·8	0·8	2·7

dehydrogenase activity was determined in the starting material as well as the individual fractions. Enzyme concentration was expressed as μmoles diphosphopyridine nucleotide oxidized per hr. per ml. Recoveries, that is, the sum of the concentrations of the individual fractions, were within 70 and 110 per cent of the starting material. To eliminate differences in recoveries, all results were adjusted to total serum lactic dehydrogenase activity (Table 1).

The results may be summarized as follows:

(1) Higher lactic dehydrogenase concentration in effusions as compared to the corresponding sera is frequently encountered in cancer and local infections, whereas in congestion, enzyme concentration is equal or lower in the transudate[1]. Due to overlap, little diagnostic significance can be attributed to these differences in total enzyme activity.

(2) In non-infected non-malignant effusions, heterogeneity of lactic dehydrogenase mirrors the serum pattern as shown in Fig. 1*a*.

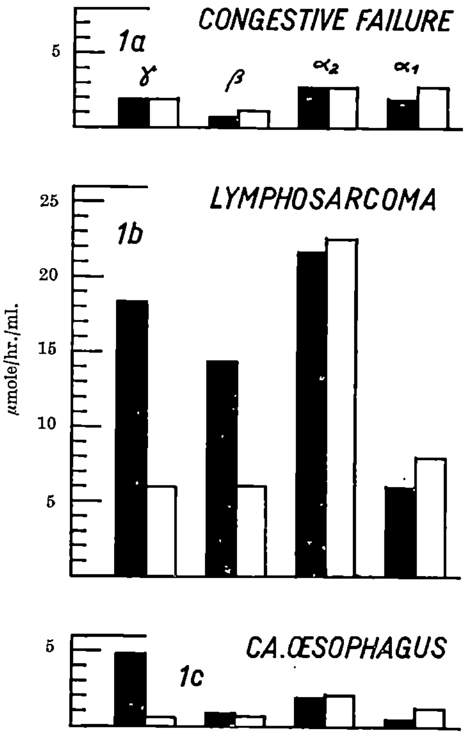

Fig. 1. Heterogeneity of lactic dehydrogenase. Black columns, effusions; white columns, serum. (*a*) 58-year-old male with congestive heart failure (serum lactic dehydrogenase 5·2 units; effusion lactic dehydrogenase 6·5 units). (*b*) 31-year-old male with generalized lymphosarcoma (serum lactic dehydrogenase 43 units; effusion lactic dehydrogenase 58 units). (*c*) 71-year-old male with metastasizing œsophageal carcinoma (serum lactic dehydrogenase 4·0 units; effusion lactic dehydrogenase 8·0 units)

(3) In malignant effusions, γ-lactic dehydrogenase is markedly increased in absolute value as compared with benign effusions, as well as relatively in comparison to the corresponding serum. The α_1 and α_2 enzymes reflect the serum pattern. The increase in the γ-fraction is independent of total lactic dehydrogenase, which may be very high, as in Fig. 1*b* (lymphosarcoma) or 'normal' (œsophageal carcinoma) as in Fig. 1*c*.

(4) If hæmolysis occurs, the heterogeneity of the pattern is distorted in comparison to serum too, but the increase is restricted to the α_1 fraction. In hæmolysed erythrocytes only an α_1 and α_2 enzyme can be demonstrated[3,6].

These findings indicate that in effusions the presence of an increased amount of lactic dehydrogenase migrating as a γ-globulin is suggestive of cancer. The number of samples investigated is too small to justify a definite statement, but the importance of the demonstration of a quantitative and possibly qualitative difference between a normal and a malignant body fluid is obvious. Warburg and Christian[9] first demonstrated abnormal leakage of glycolytic enzymes from cancer cells. Our observations suggest that, independent of the type of cancer, the leaking enzyme is primarily a γ-lactic dehydrogenase, which may be due either to selective leakage or to a distortion of the cellular lactic dehydrogenase pattern in cancer. Wieland and Pfleiderer[2] reported an increase in the slow-migrating lactic dehydrogenases ('γ-enzyme') in one bronchial carcinoma as compared with normal lung tissue, but further investigations will be necessary to settle this question. The discrepancy between effusion and serum pattern in malignancy is puzzling too. The lack of an increase in γ-lactic dehydrogenase in serum may be due to dilution, to local destruction by peptidases or to denaturation.

An Antigen in Lesions of Molluscum Contagiosum

OUCHTERLONY's technique of agar diffusion[1] has made it possible to demonstrate the presence of certain viral antigens and antibodies not identifiable by other serological means. Datt and Orleans[2], in 1958, found an antigenic substance common to vaccinia and pig pox; Taylor-Robinson and Rundle[3] have demonstrated a common antigen in chicken pox and herpes zoster. These successes prompted a re-investigation of the antigenicity of molluscum contagiosum, a large virus that produces benign skin tumours in man.

The method of Taylor-Robinson and Rundle[3] was used. Skin curettings of molluscum lesions were pooled, ground and lyophilized to give a crude antigen. Four different antigen samples were prepared; 50–150 lesions from two to five patients comprised each sample. The donors were used only once; no anæsthesia was required. The antigen suspended in saline, 3–4 mgm./ml. or 30–40 mgm./ml., was put in the central reservoir of agar plates prepared for immunological study (1 per cent (w/v) Difco agar dissolved in isotonic saline and phosphate buffer pH 7·3 and containing merthiolate 1: 10,000; wells 11 mm. apart and 5 mm. deep). Sera from (1) patients infected with molluscum contagiosum; (2) adults without the disease, and (3) uninfected children were put in surrounding wells. The plates were examined daily for 2–3 weeks.

A single precipitation band (Fig. 1) appeared in 9 of 21 patients (43 per cent), 8 of 73 adults (11 per cent), and 0 of 11 children, and was usually evident within 48 hr. Weak concentrations of antigen (4 mgm./ml.) gave positive reactions only with sera from patients having numerous (more than 50) lesions of molluscum contagiosum. All antigens displayed equal activity. Comparable concentrations of lyophilized normal skin curetted from the same donors or from normal subjects gave consistently negative results. Ground, lyophilized human warts showed no antigenicity in this system. Of the positive reactors in the adult group, four had markedly raised serum globulin-levels related to multiple myeloma or internal cancers. A fifth subject with a high serum γ-globulin had a history of infectious hepatitis. One additional subject had a false-positive serological test for syphilis without a significant electrophoretic abnormality. These alterations were absent in sera from patients with molluscum contagiosum.

These findings indicate the presence of an antigen capable of inducing antibody formation in the lesions of molluscum contagiosum. This may conform to the heat-labile antigen–antibody system reported by Mitchell[4]; he noted weak complement fixation reactions of crude molluscum antigen with sera from 3 of 14 patients infected with the virus. About half our patients with the disease had demonstrable antibodies; they were more prevalent in those patients with extensive lesions. While the positive reactions in adults can be explained on the basis of prior unrecognized infection[5], it seems curious that 50 per cent of the positive reactors had high serum globulin associated with internal malignancy; the possibility exists that a cross-reacting tumour antibody gave the observed precipitation bands. The non-infected children had been confined to an isolated ward and presumably had never been exposed to molluscum contagiosum.

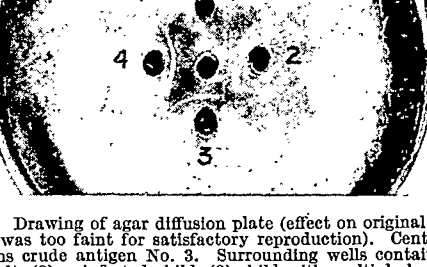

Fig. 1. Drawing of agar diffusion plate (effect on original photograph was too faint for satisfactory reproduction). Centre well contains crude antigen No. 3. Surrounding wells contain sera: (1) adult, (2) uninfected child, (3) child with multiple lesions of molluscum contagiosum, (4) adult with less than 25 lesions

Work is in progress to determine whether the crude antigen is a purely viral substance or an altered tissue antigen.

Leukæmia in the Progeny of Mice inoculated with a Leukæmogenic Virus

TEN years ago Gross first reported a raised incidence of leukæmia in mice of a low-leukæmic strain (*C3H*) inoculated when newly born with a cell-free extract of leukæmic tissue from a high-leukæmic strain (*AK*)[1]. He also observed a raised incidence in the progeny of the inoculated mice[2]. Since then, the first observation has been several times confirmed, but the second has not been reported from any other laboratory.

In the course of recent work in this Department on another leukæmogenic agent, the virus which Moloney isolated from the sarcoma 37 [3], several groups of stock albino mice ('Schofields') were injected when newly born with cell-free filtrates prepared from tissues of leukæmic mice of various breeds which had received a tissue culture-passaged sample of Moloney's virus[4]. In one experiment a new-born litter of 7 stock albinos (2♂, 5♀) were injected with such a filtrate. Leukæmia began to appear at 12 weeks of age, and 6 mice had developed leukæmia by 20 weeks. Before the appearance of the first leukæmia the mice were brother-sister mated; of their progeny of 18 (9♂ and 9♀) born when the parents were approximately 9 weeks old, 11 have become leukæmic between the 11th and 20th week of age. In the second experiment 7 new-born litters of stock albinos (a total of 46 mice) were inoculated with another filtrate. Leukæmia began to appear at the 11th week, and the incidence reached 50 per cent at 21 weeks. Among the mixed progeny (total 27) of these 7 litters, also born when their parents were about 9 weeks old, 9 leukæmias have appeared between the 11th and 20th week of age.

In a long experience of this breed of mice we have never seen spontaneous leukæmia as early as this. It occurs occasionally between 6 and 10 months of age: the cumulative incidence for the first 12 months is about 3 per cent.

Three contemporary control groups of stock albino mice of the same breed may be directly compared with the inoculated groups and their progeny:

(1) 32 untreated controls, 22 weeks old. No leukæmias.

(2) 46 mice inoculated with the same Moloney filtrate heated for ½ hr. at 80° C. These are now 24 weeks old. One leukæmia appeared at 22 weeks.

(3) 12 progeny of (2), now 16 weeks old. No leukæmias.

It would be premature to speculate at present about the mechanism of this phenomenon. Various possible modes of transmission are being investigated.

IMMUNOLOGY

Antibodies to Trophoblasts during the Post-Partum Period

RECENT investigation of homograft tolerance has stimulated speculation about the immunological relationship between mother and fœtus during pregnancy[1,2]. Since the fœtus with its placenta is genetically different from the maternal host, it can be looked upon as a homograft tolerated by the mother for nine months. Fundamental to the support of such a concept is the demonstration of an immune response by the mother to her products of conception at some time during or after pregnancy. In human beings, the syncytiotrophoblasts are the fœtal cells in direct contact with the maternal bloodstream. They invade the bloodstream and disappear[1]. It would seem, therefore, that an immune response by the mother would most likely be directed towards trophoblasts. Although experimental homograft immunity is mediated primarily through a cellular response by the host[3], the direct contact between trophoblasts and maternal blood might stimulate a humoral response as well. The large mass of trophoblastic tissue in the placenta could absorb circulating antibody effectively. This might explain previous reports of failure to detect antibodies to placenta during pregnancy[4,5]. After delivery of the fœtus and placenta, the absence of this absorptive surface might allow any anti-trophoblastic antibody to remain in the bloodstream, where it could be detected by appropriate methods.

Based on these considerations, attempts were made to demonstrate anti-placental antibody in the sera of post-partum patients. Portions of placentas obtained from normal deliveries were immediately washed in EDTA-buffered saline (0·01 M EDTA adjusted to pH 7·2) until largely free of blood. A water-soluble extract of the homogenized tissue was prepared and lyophilized for storage. Smaller portions of the fresh placenta were quick-frozen in a dry-ice-ethanol bath and stored in a dry-ice chest. The patient's blood was drawn on the fourth post-partum day and the serum tested against her own placenta in every case.

Attempts to detect a precipitating antigen-antibody system with various concentrations of lyophilized placental extracts and post-partum sera were unsuccessful. In these experiments, the direct precipitin, Ouchterlony agar diffusion and agar immunoelectrophoresis techniques were employed. Concentrated globulin fractions of the sera also failed to give a precipitin reaction. Inconclusive hæmagglutination patterns have been obtained so far, using tanned sheep red blood cells sensitized[6] with various dilutions of placental extract and tested with doubling dilutions of post-partum serum.

Positive results were obtained, however, using the fluorescent antibody method of Coons on tissue sections[7]. The globulin fraction of post-partum serum was obtained by precipitation with 20·4 per cent sodium sulphate, tagged with fluorescein *iso*thiocyanate, and absorbed with mouse and rat liver powders. Globulin from the serum of a non-pregnant normal woman was treated similarly as a control. The frozen placental samples were sectioned at 4μ in a cryostat, dehydrated in alcohol for 30 sec., and stained at room temperature. Treatment of the sections with tagged post-partum globulin for 30 min. resulted in the localization of fluorescence in all cellular elements of the villi as viewed by ultra-violet microscopy. When the section was first flooded with untagged post-partum globulin for 30 min., sites of fixation on the tissue were blocked and subsequent treatment with the tagged material failed to result in fluorescence.

Several factors unrelated to an immune response by the mother to the placenta could play a part in the fixation of globulin by placental tissue. Globulin was fixed non-specifically despite prior absorption with rat and mouse liver powders, as illustrated by the presence of some fluorescence after staining with tagged globulin from a normal non-pregnant woman. Another factor was the known ability of the placenta to transport globulin from the maternal blood to the fœtal circulation[8]. The active sites of such a transport mechanism in the section might bind tagged globulin independently of any antigen-antibody system. A third factor was the possible presence of blood-group substances in the placental tissues. These could also play a part in the fixation of post-partum serum.

These possible explanations were eliminated by flooding the sections with untagged globulin from a non-pregnant normal woman of blood group *O*. Sites of non-specific binding of protein would thus be blocked. Sites involved in the mechanism of globulin transport would also be blocked. Any *A* or *B* blood-group substance on the placental section would combine with the anti-*A* and anti-*B* antibody present in the type *O* globulin and would be unavailable for further reaction. When such a pre-treated section was treated with tagged globulin from a non-pregnant woman, no fluorescence was seen, but treatment with tagged globulin from a post-partum woman resulted in fluorescence which was limited to the cytoplasm of the syncytiotrophoblasts (Fig. 1). This reaction has been observed in each of five patients of differing parities and blood-groups thus far studied.

The evidence favours the interpretation of the binding of tagged globulin from post-partum sera by

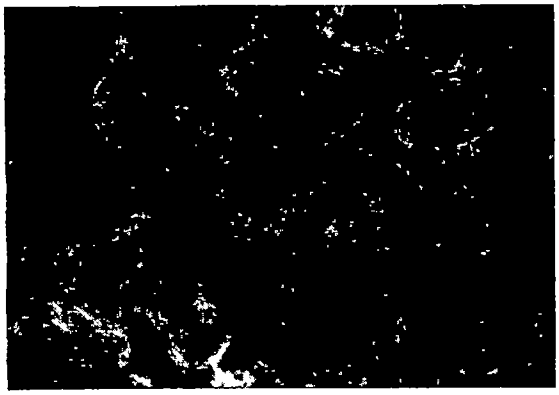

Fig. 1. Frozen section of human placenta treated with globulin from serum of a non-pregnant woman of blood group *O*, then stained with fluorescein-tagged globulin from the serum of the woman who delivered the placenta. Under ultra-violet excitation, only syncytiotrophoblastic cytoplasm fluoresces. (× 90)

the syncytiotrophoblastic cytoplasm as an immune phenomenon. An investigation designed to delineate the time of origin of this reaction with respect to possibly related events such as labour, pre-eclampsia and abortion is under way.

Specific Inhibition of Anti-*D* Antibody by Colominic Acid

IN ref. 1 it is reported that certain nucleotides specifically inhibited anti-*Rh* antibodies, and in ref. 2 that there is specific inhibition by certain monosaccharides and substances such as rutinose and streptomycin. Although some differences in the effect of these substances on anti-*C*, anti-*D* and anti-*E* were observed by both groups of workers, in general a substance that inhibited one anti-*Rh* serum also inhibited the others. More recently, Dodd, Bigley and Geyer[3] have reported that N-acetyl neuraminic acid and certain related compounds inhibit anti-*D* but not anti-*C* or anti-*E* ; this is a greater degree of specificity than that claimed in the first two reports.

We have confirmed the work of Dodd, Bigley and Geyer. In addition to the compounds tested by them, we have found that colominic acid, a substance produced by certain strains of *Escherichia coli* and shown probably to be a polymer of N-acetyl neuraminic acid[4,5], inhibits anti-*D*, but not anti-*C* or anti-*E*, in relatively low concentration (0·006 *M*).

In addition to the interesting implications of these observations for the structure of the *Rh* antigens, we believe our last observation is of possible practical importance. Colominic acid is stated[5] to be non-toxic and non-antigenic, and could undoubtedly be produced in quantity if necessary. We are therefore proposing to try it clinically to neutralize the anti-*D* in *Rh*-sensitized pregnant women and thus possibly prevent erythroblastosis in the unborn child.

This work was supported by research grants (*H*–1076 (*C*8), *RG*–4704 (*C*4) and *RG*–6939) from the National Institutes of Health, and a research grant (*NSF* G–5131) from the National Science Foundation. We are indebted to Dr. W. F. Goebel for a sample of colominic acid and a culture of *E. coli* K_{235}.

BIOLOGY

Hydrogen Ion Concentration, Plankton and Fish in Fresh-water Eutrophic Lakes of India

DAS *et al.*[1] have recently published results on the quantitative and qualitative aspects of plankton of some eutrophic fresh-water lakes of Uttar Pradesh, India ; but no satisfactory information is available regarding the physico-chemical factors bearing upon them. Some work on related fields has been done by Chacko *et al.*[2] and Alikunhi[3], but their results deal only with part of the season in fish-hatching tanks and small bodies of water. In order to get detailed information regarding *p*H and plankton, regular weekly quantitative hauls were made and water samples obtained in 'Pyrex' glass-stoppered bottles. Hydrogen ion concentration was determined for each sample colorimetrically by using Helige comparators and Helige indicator solutions in daylight so far as possible in the field. Carbon dioxide was estimated by making use of phenolphthalein as indicator and the titration was done in Nessler jars in the usual way.

The investigations show that *p*H values range from 7·2 to 9·2 during the year. A high *p*H is observed in the months of July and August, when the average is about 8·6. But the values decrease during September and October and reach 7·4 in the last two weeks of October. November and December maintain rather constant values, but January shows a sudden increase in *p*H, reaching 8·8 in the third week; finally, a further rise occurs and reaches a maximum of 9·2 in the first week of February. In March *p*H values are still as high as 9·0, but show a fall to 8·0 in the last week of April. Finally, in the months of May and June, there is sharp decline in *p*H to 7·2.

The plankton records for the same period show that high *p*H values in the months of July and August coincide with the first monsoon phytoplankton peak. Then the decrease in *p*H during September–December can be attributed mainly to the zooplankton peak, along with the decomposition of organic matter caused by death and decay of zooplankton. Again a high *p*H in the months of February and March was observed to be accompanied by the blooming of Myxophyceae, causing an increase in phytoplankton. The lowest *p*H values were obtained during May and June, when there was an abundance of zooplankton and lack of phytoplankton.

It has also been observed that high *p*H values of water coincide with low values for carbon dioxide, and with the phytoplankton peaks, while low *p*H values coincide with high concentration of carbon dioxide in water during the zooplankton peak periods. This appears to be due to the fact that increase in phytoplankton causes photosynthetic activity which uses up dissolved carbon dioxide, and thus the *p*H values are raised in February and March. In the summer months, due to the concentration of aquatic animals (fishes, molluscs, etc.) in the decreased amount of water, combined with the abundance of zooplankton, the concentration of carbon dioxide increases and *p*H values reach a minimum. It is thus clear that, generally, high *p*H means high phytoplankton and low zooplankton; whereas low *p*H means low phytoplankton and high zooplankton in ordinary circumstances.

It has recently been observed (Das, unpublished work) that more fishes are present in natural lakes with a *p*H range of 7·2–8·2, but decline rapidly in highly alkaline waters which remain above *p*H 9. As no Indian eutrophic lakes have been found with a *p*H less than 7·2, fish fertility appears to be indirectly dependent on the *p*H of such bodies of water. Thus a change of environment due to change of *p*H may affect the productivity of fish in fresh-water lakes and tanks. This aspect is now being studied.

Littoral Interstitial Species from Anglesey representing Three Families new to Britain

In 1956 a brief investigation by Dr. B. Swedmark of beaches in the Anglesey area revealed a well-developed microfauna. A more intensive survey is now in progress, and many typical interstitial species have been found.

Some of the most interesting recent discoveries have been made in the low-water neap zone at Traeth Bychan, a gently sloping beach of coarse sand on the east coast of Anglesey. Three small molluscs belonging to the Pseudovermidae, a nudibranch family new to Britain, have been found in this habitat. They resemble *Pseudovermis schulzi* Marcus and Marcus more closely than any other species described. All three measured 3–3·5 mm. in length when extended, but were unfortunately immature. The shape of the radular plates together with the presence of eyes seem to confirm the identification as *P. schulzi*, but there were as many as fifteen body papillæ and an equal number of cnidosacs (Fig. 1). A maximum of five papillæ was given as a diagnostic feature in the original description. The cnidoblasts were all of one type, penetrants 5·5μ long and 4μ broad with a thread up to 70μ long when discharged. They were found to be identical in size and structure with those of the hydrozoan *Halammohydra vermiformis* Swedmark and Teissier, which has been found in the same area of beach. It is thus highly probable that this *Pseudovermis* species preys upon *H. vermiformis*. Apart from the suggestion by Dr. E. Marcus that the Brazilian *Pseudovermis salamandrops* Marcus derives its nematocysts from *Psammohydra nanna*, Schulz[1], no previous information concerning the food of pseudovermids is available.

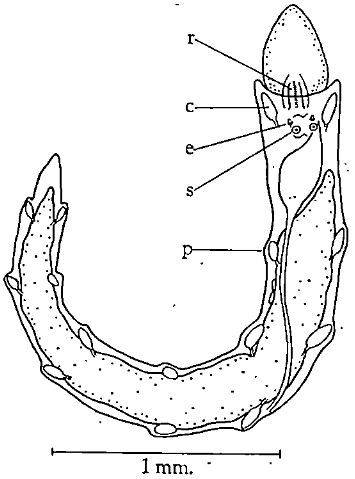

Fig. 1. *Pseudovermis* sp. from Anglesey. Dorsal view. *c*, cnidosac; *e*, eye; *p*, body papilla; *r*, radula; *s*, statocyst

A second species of *Halammohydra*, *H. schulzei* Remane, has been found in the Menai Straits among coarse shell gravel exposed at low water on spring tides. The family Halammohydridae had not previously been recorded from Britain, but an unidentified species has since been reported from the Isles of Scilly[2].

Last August a sample of sand from Traeth Bychan which contained several young *H. vermiformis* yielded a curious interstitial annelid. Further examples of this animal recovered recently prove it to be the sedentary polychæte *Psammodrilus balanoglossoides* Swedmark belonging to the Psammodrilidae Swedmark. This constitutes the third new family from this one habitat to be added to the British fauna list.

Response to Series of Subliminal Stimuli; an Ethological Method for investigating the Properties of Nervous Systems

Queen ants of genus *Formica* react to mechanical disturbance of the nest by running downwards to the deepest chambers. In laboratory colonies a series of shocks could result in a reaction, although one similar shock was too small to produce any visible effect.

To investigate this further, three separate queens of *F. fusca* L., without workers, were subjected at the same time to series of nearby taps on the bench with constant periodicity throughout each series and constant strength throughout this work. The periodicity was changed for different series and the

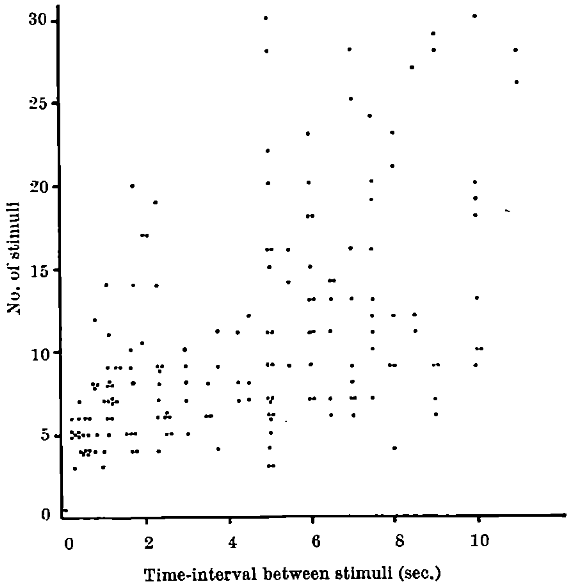

Fig. 1. The relation between the number of mechanical shocks necessary to produce an escape reaction by queen *Formica fusca* L., and the time-interval between the shocks

range of time-interval (t) between taps was 0·2–11·0 sec. Fig. 1 shows the number of taps (n) needed for a reaction plotted against t (regression analysis of log n on t; $P < 0\cdot001$).

There are several causes of the wide variance of these results, including: (i) differences in the internal state of the animals; (ii) differences in their stance; (iii) changes in temperature (range 21·3–24·5° C., mean 23·0° C.); (iv) other mechanical shocks in the same building cannot be completely discounted, but were small compared with the deliberate stimulus, and the reaction always occurred immediately after a deliberate stimulus. These causes are not expected to bias the results and are, for the present, ignored, although the method may provide opportunities for measuring the effect of important factors.

Various difficulties in observation and interpretation were encountered. The reaction varied from a change of posture (a raising of the head and thorax with extension of the antennæ) to rapid running, and in one in eight experiments a queen did not respond in spite of prolonged stimulation. This queen was ignored in this particular experiment, if it had not responded to three times as many taps as taken for the last of the others to react. Only one response, out of 172, was given to the first stimulus and the other queens in this experiment took 6 and 7 taps to react. Habituation did not appear to be an important factor, but at least 30 min. was allowed to elapse between experiments. Isolation of the queens from workers and brood was not relevant either, since a colony exposed to the same conditions at the same time showed similar behaviour with the queen usually reacting before the workers.

Evidently, there is a threshold of some nervous change which has to be reached before reaction occurs. This change shows temporal summation and can be retained for more than 10 sec. although it is gradually lost after stimulation. Exponential decay fits the results better than linear decay and, if it is exponential, its average half-life is estimated to be at least 30 sec. (since, if when $t = 0$, $n = N$, there is a vertical asymptote at the value of t during which $1/N$th of the change decays).

Unless facilitation of sense organs to subliminal stimuli can contribute significantly, these long periods of activation are due to summation and decay of activity in a nervous centre controlling escape behaviour. This centre may be an 'instinctive centre' in the sense of Tinbergen[1] and the activity may be related to the 'stored energy' of Lorenz[2] which is also required to reach a threshold before setting off behaviour.

Enhanced Plant-Growth with Two Systemic Insecticides

In the search for better methods of control of the red-legged earth-mite, *Halotydeus destructor* (Tuck.) (Acarina : Eupodidae), and the lucerne flea, *Sminthurus viridis* (L.) (Collembola : Sminthuridae), seeds of Dwalganup subterranean clover, *Trifolium subterraneum* L., were treated with the systemic insecticides demeton and methyl demeton before sowing. The seed, dampened with milk, was tumbled in a container with 8 per cent of its weight of a charcoal-based dust containing 50 per cent of the insecticide. Seeds were sown, at the rate of 50 per 8-in. earthenware pot, in sand fertilized with potato 'E' manure at the rate of 1 cwt./acre. (Potato 'E' manure contains 3·5 per cent N, 15·5 per cent P_2O_5 and 8 per cent K_2O.) The pots, of which there were three for each treatment, were kept in a glasshouse and watered at least every second day.

The emergence was 96 per cent in untreated seed; 93 per cent in the demeton treatment and 59 per cent in the methyl demeton treatment. Seedlings removed from the demeton treatment were toxic to both pests for up to 11 weeks after sowing, whereas toxicity was lost in the methyl demeton treatment after about 7 weeks. Demeton-treated seeds produced pale cotyledons and stems, whereas those treated with methyl demeton produced plants which were more heavily pigmented than normal. In both insecticide treatments the early growth of the seedlings was slightly retarded. Despite this, the plants arising from the treated seed later grew more vigorously than those in the control pots.

Three months after sowing, all plants were carefully removed from the pots and the weights of the green tops and of the roots recorded. The results are shown in Table 1. The increased yield in the pots sown with seed treated with demeton and methyl demeton amounted to an additional 39 per cent and 24 per cent respectively ($P < 0\cdot05$). There was a highly significant increase in the weights of the individual plants ($P < 0\cdot001$), but no significant differences in weight of roots. In the methyl demeton treatment it is possible that part at least of the increase in individual plant weight may have been a response to reduced seedling competition.

There was virtually no insect or mite attack on the plants in the glasshouse, and certainly insufficient to account for such large differences of yield. Small increases in growth have since been observed in outdoor pot tests with phorate ('Thimet') and *PP*175 ('Sayfos'), although no precise measurements were

Table 1. EFFECT OF DEMETON AND METHYL DEMETON APPLIED AS A SEED TREATMENT ON THE YIELD IN POTS OF THE GREEN TOPS AND ROOTS OF SUBTERRANEAN CLOVER

Treatment	No. plants at harvest	Yields (gm.)			
		Total tops	Mean tops per plant	Total roots	Mean roots per plant
Control	127	180·8*	1·42†	137·1	1·09
Demeton	125	250·4*	2·04†	148·0	1·18
Methyl demeton	86	223·7*	2·60†	126·1	1·47

* $P < 0·05$ † $P < 0·001$

taken. The phorate used was a 44 per cent charcoal-based dust whereas the *PP*175 was an 80 per cent wettable powder. Similar unexplained increases in growth following seed treatment with phorate and demeton were reported[1,2].

Clearly, these insecticide seed-treatments had some marked beneficial effect other than the direct killing of insect or mite pests. Perhaps there was some influence on the rhizosphere microfauna or flora, or possibly the transmission of virus diseases was inhibited. Whatever the explanation, there appears to be some real response worthy of further investigation.

Effects of Gibberellic Acid and Allogibberic Acid on Flowering and Internode-Length in *Pisum sativum*

SEVERAL workers[1,2] have shown that gibberellic acid causes an increase in internode-length in peas, especially in the dwarf (*le*) varieties where the increase may be as great as 500 per cent. In addition we have shown that gibberellic acid delays flowering by 1–2 nodes in tall (*Le*) or dwarf (*le*) and late (*Sn*) or early (*sn*) varieties[2]. Segregation of alleles at the *Le* and *Sn* loci has a number of overlapping effects[3]. It thus appears that genes at both loci may be working by way of some aspect of gibberellin metabolism. Accordingly we have tested the effect on flowering and stem-length of peas of a number of compounds related in structure to gibberellic acid. We are indebted to Dr. P. W. Brian (Imperial Chemical Industries, Ltd.) for the gift of the compounds used.

The compounds were applied as a solution in absolute ethanol to the dry seed of the early, dwarf variety, Massey, at a concentration of 0·4 μgm. per μl. Doses of 1, 2, 8, 16 and 32 μgm. were regulated by varying the volume of the solution applied by means of a micropipette. The ethanol rapidly evaporates leaving the compound on the testa of the seed. The seeds were germinated in moist vermiculite and transplanted as seedlings into soil. Comparable doses of pure ethanol had no effect on the subsequent growth of the plant.

Compounds tested include methyl gibberellate, gibberellin *C*, gibberellenic acid, gibberic acid and allogibberic acid. Methyl gibberellate produces similar responses on both flowering and stem-length to gibberellic acid, but is not so active. Gibberellin *C* and gibberellenic acid were inactive at doses of 1 and 2 μgm. per plant. At 32 μgm. they have an effect equivalent to a dose of less than 1 μgm. of gibberellic acid. The effects of these two substances are most probably attributable to contamination with gibberellic acid (Dr. Brian has informed us that it is very difficult to prepare pure samples of these compounds). Gibberic acid had no effect on either growth or flowering at any of the concentrations tested. Allogibberic acid had no effect on stem-length but appeared to cause a small delay (0·5 node) in flowering.

In a more detailed study of the effect of allogibberic acid, four chemical treatments (0, 1, 10 and 100 μgm. of allogibberic acid per plant) were combined factorially with two photoperiods (short days of 8 hr. and long days of 18 hr.). A randomized block design of 20 plants per treatment was used. Experimental procedure was the same as in the previous experiment except that the different doses were applied in each case in the same volume (10 μl.) of ethanol.

Flowering is delayed to a higher node by allogibberic acid. The delay shows a steady increase from zero at a dose of 1 μgm. to a maximum of 0·65 node (statistically significant at the 1 per cent level) at the highest dose of 100 μgm. per plant. In contrast, allogibberic acid does not alter internode-length at any of the concentrations tested. The photoperiod treatment and the photoperiod-chemical interaction are not significant for either node of first flower or internode length. The long- and short-day results have been combined and plotted in Figs. 1 and 2 together with results from a previous experiment on the effect of seed treatment with gibberellic acid on the same pea variety, Massey.

Fig. 1 illustrates that gibberellic acid and allogibberic acid both cause a delay in flowering. The effect of gibberellic acid is approaching a maximum

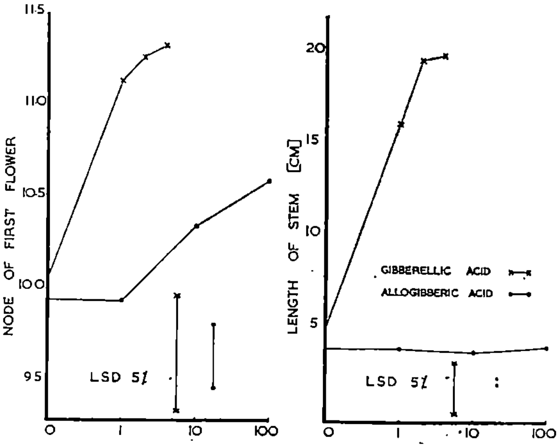

Fig. 1 Fig. 2

Figs. 1 and 2. The node of first flower and the length of stem in cm. between nodes 1 and 4 are shown for various dose-levels of gibberellic acid and allogibberic acid. The compounds were applied in ethanolic solution to the dry seed of an early dwarf pea variety, Massey. The cotyledonary node is taken as zero at a dose of 4 µgm. per plant, whereas the delay caused by allogibberic acid may still be increasing at the maximum dose of 100 µgm. The delay achieved with this highest dose is only about half the maximum delay achieved with gibberellic acid. Fig. 2 contrasts the effect of the two compounds on stem-growth. Two µgm. of gibberellic acid causes about a 400 per cent increase in stem-length whereas 100 µgm. of allogibberic acid has no effect. These results on stem-growth are in agreement with those of Cross[4] and Brian *et al.*[1,5].

The chemical structures of gibberellic acid, allogibberic acid and gibberic acid have been established by Cross *et al.*[6,7]. Chemically, allogibberic acid is a primary degradation product from gibberellic acid and differs from it only in ring *A*. Biologically, allogibberic acid has lost the power to stimulate elongation in dwarf peas but is still capable of delaying flowering. Gibberic acid, which is another degradation product derived from allogibberic acid by a Wagner–Meerwein rearrangement, seems to have lost both activities. The delay in flowering induced by gibberellic acid or allogibberic acid is not altered under different photoperiods and it is unlikely, therefore, that either substance is the flower inhibitor (colysanthin) which we have suggested is produced by the dominant *Sn* gene of late varieties of peas[3].

One of us (I. C. M.) acknowledges the assistance of a Commonwealth Scientific and Industrial Research Organization research studentship. The Rural Credits Division of the Reserve Bank of Australia has helped us by providing funds for technical assistance, apparatus and glasshouses.

Susceptibility to Leaf Blight, caused by *Cochliobolus heterostrophus*, in Nigerian Varieties of Maize

LEAF blights on maize are prevalent, particularly in the forest areas of Southern Nigeria. One of the commonest of these pathogens is *Cochliobolus heterostrophus* (Dreschl.) Dreschl., already recorded in West Africa in 1928 in Ghana[1] and in 1933 in Nigeria[2]. The lesions develop in abundance on the leaves, from the lower ones upwards. A typically infected maize plant was taken at tasselling time and the area of the various leaves attacked by the fungus determined (Table 1).

Table 1. LEAF AREA AND PERCENTAGE OF THE AREA ATTACKED BY *C. heterostrophus* OF A TYPICALLY INFECTED MAIZE PLANT. LEAVES NUMBERED FROM BASE TO TOP

Leaf No.	Leaf area (cm.^{2})	Percentage of leaf area attacked
1	487	20·1
2	619	11·4
3	818	9·8
4	902	10·9
5	938	8·0
6	993	10·4
7	1,037	8·8
8	988	4·2
9	905	5·6
10	825	2·6
11	758	3·1
12	741	0·6
13	561	0·3
14	431	1·1
15	239	0·8
Total	11,242	6·3

The fungus causes a premature dying back of the leaves from the base onwards, around the time of tasselling. Heavily infected plants lose their lowest leaves earlier and have no more green leaf area within approximately 3 wk. from tasselling, that is, before the grains on the ears are properly formed.

Most of the varieties introduced as breeding material, mainly from the Americas, proved to be very susceptible to this fungus. The most susceptible variety was Coahuila-8 from Mexico. The lowest scores were obtained on the synthetic variety *ES*2, a local selection from the Mexican variety Rocamex 520–*C*. However, even this selection has a considerable reduction in leaf area, in seasons favourable to the pathogen.

For the purpose of a survey, a collection was made of West African maize varieties[3] of which approximately 650 are maintained at Moor Plantation, Ibadan. The main part of this collection consists of Nigerian varieties. Those local varieties of maize were grown at Ibadan during the early season of 1959 (March–July) with 30 plants per variety. Each plant was assessed quantitatively on the occurrence of lesions caused by *C. heterostrophus* with the aid of an arbitrary key. Three leaves were assessed per plant and a mean calculated. Three levels of attack were recognized, roughly corresponding with 0–1 per cent (intensity 1), 2–5 per cent (intensity 2) and 6–10 per cent or more (intensity 3) of the leaf area attacked by the pathogen. This was done in order to obtain information on possible sources for resistance.

The early season of 1959 was favourable for the development of the fungus and provided an excellent opportunity to screen the collection on resistance. The results have been mapped by indicating the average intensity score of *C. heterostrophus* on the various maizes on the place of their origin (Fig. 1).

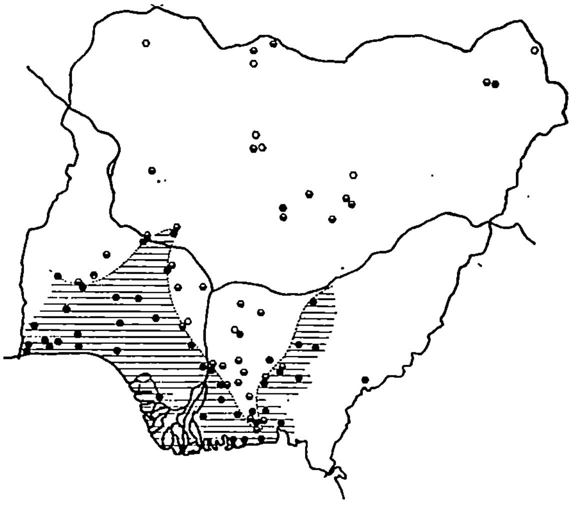

Fig. 1. Map of Nigeria showing the distribution of susceptibility and resistance to *Cochliobolus heterostrophus* in local maize varieties. ●, Intensity 1; ⊖, intensity 2; ○, intensity 3 (scores are mapped on the place of origin of the varieties)

It is noteworthy that, apart from a few exceptions, the more resistant varieties (intensity score 1) have their origin in the forest belt of the south (hatched area on Fig. 1). This area comprises the main maize-producing area of Nigeria in the drier parts of the rain forest and derived savannah of the western region[4]. East of the River Niger, however, a broad front of less-resistant varieties invades the densely populated areas of the eastern region and reaches very far south. Within this triangle the varieties have white or yellow, floury (soft endosperm) or flinty (hard endosperm) grains. The majority of the western region varieties, however, are white and soft-grained. The same is true for varieties in the south and south-east of the eastern region. The northern maize varieties, however, are typically yellow and hard-grained.

Trade and accidental movements of maize grains could be responsible for the phenomenon of maize varieties susceptible to leaf blight in a zone where natural selection would have eliminated those and actually did to the west, south and south-east of the area. In several places just north of this wedge (Keffi, Lafia) 'Southern' floury varieties are cultivated for sale on markets where 'Southerners' have caused a demand for those grains, although the local population often dislikes this type. It is also known that a trade of maize occurs within the area from north to south[5], from the less to the more densely populated areas (for example, from Idoma and Igala divisions towards Onitsha).

It is suggested that the resistance to the Nigerian strains of *C. heterostrophus* is a recessive character, probably based on several genes. The fact that the western region varieties all had a relatively high resistance to this leaf blight would tally with the fact that there is little trade of maize into the area. The influx of seed into the eastern region could then explain the higher susceptibility of the maize varieties in the wedge, and the low number of cases of 'resistant' varieties found in Northern Nigeria, in spite of the fact that the numerous 'Southern' inhabitants of the northern region have, doubtlessly, taken southern maizes to the north, would then be understandable.

Diurnal Variation in Transaminase Activity in the Cactus Plant

THE rhythmic acidification and deacidification occurring in cactus and other succulent plants may be expected to be associated with rhythmic alteration in the activity of enzymes involved in the formation and transformation of the organic acids. A change in the activity of an enzyme may be envisaged as being brought about by altering the total amount of catalytic site available, that is, by the synthesis or destruction of enzyme protein, or by the elaboration or removal of activator or inhibitor molecules from the site of enzyme action, or by the accumulation of products of reaction. It has been reported from this laboratory[1] that cactus plants growing in garden soil in the open showed a marked diurnal variation in aldolase activity and it was suggested that the peak of its activity, which was reached in the dark, was linked with the breakdown of carbohydrate to the 3-carbon atom acceptor of carbon dioxide. Continuing the above investigations, we have found that the phylloclades of *Nopalea dejecta* grown in the open under natural conditions of light and darkness show a remarkable diurnal variation in glutamic oxaloacetic transaminase activity.

The transaminase activity was determined by the colorimetric method of Tonhazy *et al.*[2] on homogenates of pooled samples of phylloclades collected at 4-hourly intervals over a 24-hr. period in February and in March of this year. A unit of enzyme was defined as the amount which gave rise to 1 μgm. of pyruvic acid at 30° C. in 30 min. at *p*H 7·4. Specific activity of the enzyme was calculated as units per mgm. dry weight of tissue. Protein was estimated by the biuret method of Gornall *et al.*[3] after precipitation with trichloracetic acid, and total nitrogen by the micro-Kjeldahl method. In some experiments the non-protein nitrogen was determined by Kjeldahl digestion of the centrifuged supernatant from the precipitate formed with trichloracetic acid.

The results reported in Table 1 show that the transaminase activity was maximum at 4 p.m. and was markedly reduced at 8 p.m., to be followed by a further abrupt drop. The enzyme was thereafter maintained at an extremely low level, until noon, when the activity began to increase. When equal volumes of the homogenates from material collected at 4 p.m. and at 8 a.m. were mixed, it was found that the enzymic activity of the mixed homogenate was almost exactly the arithmetic mean of the individual activities of the two samples. This indicated that the observed diurnal alteration in enzymic activity was due essentially to changes in the quantity of active enzyme and not to the presence of activator or inhibitor. There was a rhythmic alteration also in the protein content, which, however, was much less pronounced than that of transaminase activity. Calculated on the basis of dry weight of tissue, the protein content was high in the day-time and low during the night.

Saltman *et al.*[4] demonstrated that during the exposure of leaves of *Bryophyllum calycinum* to

labelled carbon dioxide in the dark for 1 min.–2 hr., radioactivity was incorporated into the acids of the Krebs tricarboxylic acid cycle and amino-acids such as glutamic acid, aspartic acid and alanine. The authors considered that the amino-acids arose from the α-keto acids of the cycle by transamination reactions. The extremely low activity of transaminase observed by us at night may be indicative of predominance of organic acid production during dark fixation of carbon dioxide in cactus, with minimal transformation of α-keto acids to amino-acids. Conversely, the high activity of the enzyme commencing at noon and reaching an abrupt peak at 4 p.m. may be associated with increased amino-acid synthesis in the day-time. Our work on non-protein nitrogen of cactus tissue has been of a preliminary nature, but estimations of total protein reveal a rhythmic increase in the day-time.

Shortening the Juvenile Phase of Apple Seedlings

Apple seedlings usually take 7–14 yr. to come into bearing. Many attempts have been made by plant breeders and others to reduce this juvenile phase, in order to obtain an earlier assessment of new seedlings.

Variations in pruning, nutrition and cultural practices have failed to shorten this juvenile period. By working seedlings on the dwarfing rootstock *MIX*, Tydeman[1] was able to shorten the juvenile phase by approximately one year. This practice has the disadvantage that many clones of this rootstock carry virus diseases and will consequently infect the new seedlings. It is therefore necessary to maintain the unworked seedling as well as its progeny worked on the rootstock, a system which doubles the land required by the plant breeder.

It has been found that apple seedlings worked on apomictic seedling rootstocks from *Malus sikkimensis* have a shorter juvenile phase than when worked on *MIX*; and since the apomictic seedlings are virus-free it should not be necessary to maintain the original seedling.

In an experiment begun in 1956, three crosses were made from which twenty-five seedlings were raised. These were multiplied vegetatively during their first year by budding on to one-year-old seedlings of *M. sikkimensis*; the young trees were later transplanted into the orchard.

It can be seen (Table 1) that 15 per cent of the trees were flowering 3 yr. after budding and 53 per cent after 4 yr. Since about one-third of the trees were fruiting by the end of their fourth year, and were carrying an average of seven fruits, it was possible to obtain an early assessment of the value of these new seedlings. None of the original twenty-five seedlings planted alongside for comparison has fruited during the same period, although both sets of trees have been treated similarly and no pruning has been carried out.

The possibility that other apomictic species may have a similar effect on the juvenile phase of apple seedlings worked on them is being investigated.

Cactus Virus in the United States

Since the first report by Molisch[1] of the presence of proteinaceous spindles in the cells of certain cacti, a series of researches has been made demonstrating the association of virus with the spindles and with amorphous inclusions[2].

The immediate source material for these investigations has been exclusively from European greenhouses and botanical gardens. We can now report the presence of virus in cacti cultivated in the United States.

Characteristic cigar-shaped spindles, usually one, but occasionally two to the cell, have been observed, mainly in the hypodermal cells of free-hand sections of pads of *Opuntia monacantha f. variegata* and of four other kinds of flat-padded opuntias cultivated in Montana and California. We examined one field sample of *O. lindheimeri* shortly after it was collected in Texas. No inclusions associated with virus were found. Such inclusions were reported previously to be present in a cultivated sample of this species[2]. No spindles have been found in pads of twenty cactus species examined shortly after field collection in Arizona, California and Montana.

In all cases, virus transmission was successful, as judged by the development of spindles, when sap from spindle-containing specimens was injected into or rubbed on the previously spindle-free pads of *Opuntia* species growing in the Montana State University greenhouse and the University of California at Los Angeles Botanical Garden.

No external symptoms appeared when representatives from the families Leguminosae, Solanaceae, Chenopodiaceae, Cruciferae, Tropaeolaceae or Cucurbitaceae were inoculated. Electron micrographs made from spindle-containing pads by the quick-dip method[3] showed two groups of elongated particles, with one length peak at 515 mμ (similar to cactus virus 1 (ref. 4)) and another at 300 mμ.

We wish to thank H. O. Agrawal and R. A. Solberg for help with some experiments, and Dr. L. Bos for the electron microscopy. This work was supported by the U.S. Public Health Service Grant No. *E*-596(*c*).

Antimicrobial Substances from Ferns

It has been almost twenty years since Osborn[1] reported his now classical work on antimicrobial substances from green plants. Since that time the literature accumulated on this subject has been voluminous[2]. The vascular plants tested, however, have been essentially spermatophytes, with little attention to the pteridophytes. This work is concerned with the extraction of antimicrobial substances from thirty ferns collected at the Brooklyn Botanical Gardens. The specimens were selected at random, and the cut fronds were allowed to dry in air for at least one week before testing. Four additional dried ferns were obtained from other sources and likewise tested.

Extracts of the plants were prepared in the following manner: 15 gm. of pulverized material were added to 100 ml. of methanol and macerated in a Waring blendor for 3 min. and filtered. Filter-paper disks (6·35 mm. diam.) were saturated with the extract and allowed to dry for 3 hr. The surface of nutrient agar dishes was seeded with 0·5 ml. of a 48 hr. bacterial broth culture while 0·5 ml. of a one-week-old fungal culture was used to seed Sabauraud maltose agar dishes. The prepared disks were placed on the surface of the seeded dishes and incubated. All micro-organisms were incubated for 48 hr., the bacteria at 37° C., the fungi and *Erwinia caratovora* at 22° C. The zones of inhibition were measured from the disk edge to the zone edge and recorded in mm.

In Table 1 is listed the ferns and their zones of inhibition against 8 bacteria. No zones of inhibition were produced against *Aspergillus niger* ATCC 6277, *Candida albicans* ATCC 10231, *Gibberella fugikuroi* NRRL 2284, and *Helminthosporium trucicum* ATCC 11535. The results indicate that antibacterial substances were extracted in the methanol-soluble fraction from 33 of the 34 specimens tested and that plant pathogenic bacteria are more susceptible than human pathogens. This may perhaps explain the relative resistance of ferns to bacterial invaders. Additional extracts are being prepared in this Laboratory and will be the subject of future reports.

Introduction of the Potato into Western and Central Europe

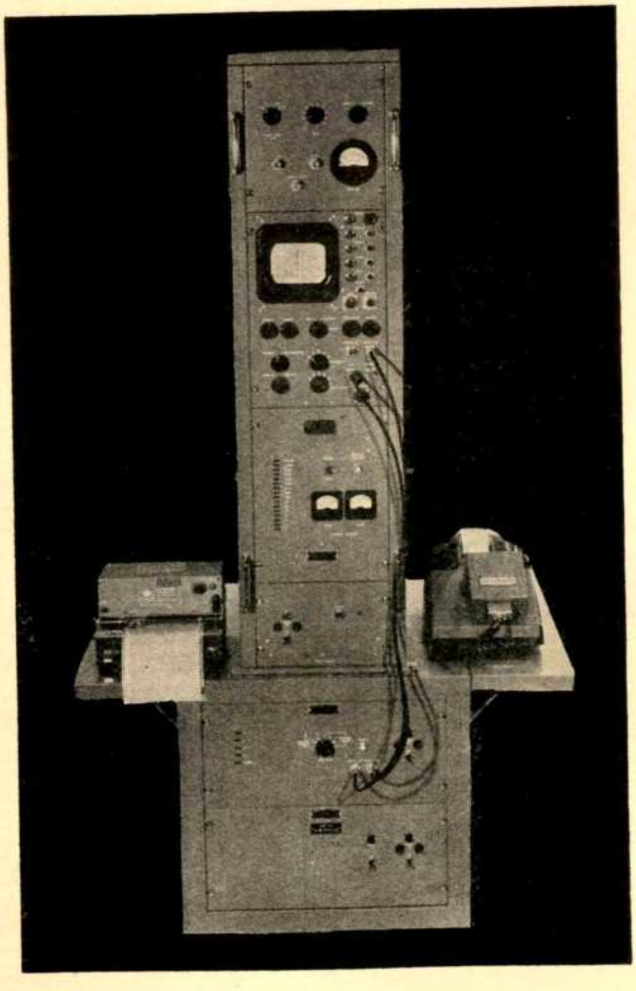
The botanist Clusius, who prepared one of the first descriptions of the potato plant[1], indicated not only the time (the beginning of 1588) of his receiving from Philippe de Sivry (Prefect of the City of Mons, Belgium) two potato tubers and a berry, but also when Philippe de Sivry himself obtained the tubers. Clusius wrote that Philippe de Sivry had received it in the preceding year from a certain friend of the Papal Legate in Belgium under the name of 'Taratouffli'. ("Is a familiari quodam Legati Pontifici in Belgio se

CDC's PROVED PERFORMANCE

100-CHANNEL PULSE HEIGHT ANALYZER

CHALK RIVER KICKSORTER

Manufactured by Computing Devices of Canada, Limited, from specifications prepared by Atomic Energy of Canada, Limited.



The convenience and speed of automatic printout can be obtained by adding a Decimal Scaler, a Print Control Unit, and an Electric Printer as accessories, shown with the Kicksorter. Provision is also made in the circuitry for the addition of a Pen Recorder for more accurate analog output.

88% TRANSISTORIZED

- Printed Circuitry
- Low Maintenance—High Reliability
- Low Power Consumption—120 Watts
- No Ventilation or Cooling Problems

VERSATILE DATA PRESENTATION

- Oscilloscope Display
- Binary Manual count readout allows the count on any channel to be displayed in digital form.
- Magnetic Core Memory—65,535 counts can be stored per channel.
- Permanent Count Storage—sixteen magnetic cores for each of the 100 channels.
- Highly Versatile—can be modified to accommodate most applications which require additional features.

The Chalk River "Kicksorter" is designed to span random pulses of various amplitudes and shapes, sort them according to amplitude into 100 channels, and store a record of the counted pulses in a magnetic core memory. This computer, with its magnetic core memory and versatile data display system, makes it possible to observe the pulse amplitude spectrum as it accumulates or after it has accumulated.

In addition to its wide use in gamma spectroscopy, the "kicksorter" has many applications in medical research, neutron time-of-flight studies, radioactive fallout studies, shielding studies, oil well and uranium logging, neutron activation analyses, measuring of radioactivity in humans, and other areas.

The analyzer is designed so that information accumulated may be displayed or read out in various ways. Data may be observed on the oscilloscope, or information already accumulated in the memory core may be displayed on the screen, plotted on a strip chart recorder, or printed out in decimal form on an automatic printer.

acceptisse scribebat, anno praecedente Taratouffli nomine"). Roze, the author of *Histoire de la Pomme de Terre*[2], translating into French Clusius's description, erroneously omitted the words "in the preceding year". The same mistake was repeated by Redcliffe Salaman in his monograph *The History and Social Influence of the Potato*[3]. Fuess[4] in Germany, as a result of Roze's fault and evidently having no original text by Clusius, erroneously supposed the time of potato introduction into Mons to be the year 1566. Roze admitted the second mistake in the French translation of Clusius's potato diagnosis. Clusius describes the shape of his potato berries as "orbiculata". That strictly means not globose or rounded but disk-shaped, and his description is very true to the picture. In Salaman's English translation of Clusius's diagnosis, the same lack of punctiliousness is observed.

Disk-shaped berries are rare to-day among cultivated potatoes, and this morphological feature, as well as some other ones (namely, numerous stolons and tubers, very different tuber size, rather late tuberization, probably deep eyes, weakly dissected leaves with short leaflet stalks, leaflets without elongated apices, numerous blossoms, calyx sharply limited from the top of the pedicels, according to the picture probably spear-leaved lobes of the calyx, deeply dissected calyx and corolla, green rays of stella, evidently short anthers (in broad cone ?) and odoriferous flowers), lead me to suppose that at least one tuber of two, or a plant from the berry which Clusius received in Vienna from Philippe de Sivry, belongs to the circle of forms *S. andigenum* Juz. et Buk. convarietas curtibaccata Lechnovitch, from South Peru. The present-day German potato (var. Jubel) has the same type of berries, anthers, and leaves and is, perhaps, connected with Clusius's material. The date of at least one, probably the earliest and possibly the chief, introduction of the potato into Western and Central Europe is quite clear.

ENTOMOLOGY

Air-Swallowing : a Mechanism in Photic Reversal of the Beetle *Trypodendron*

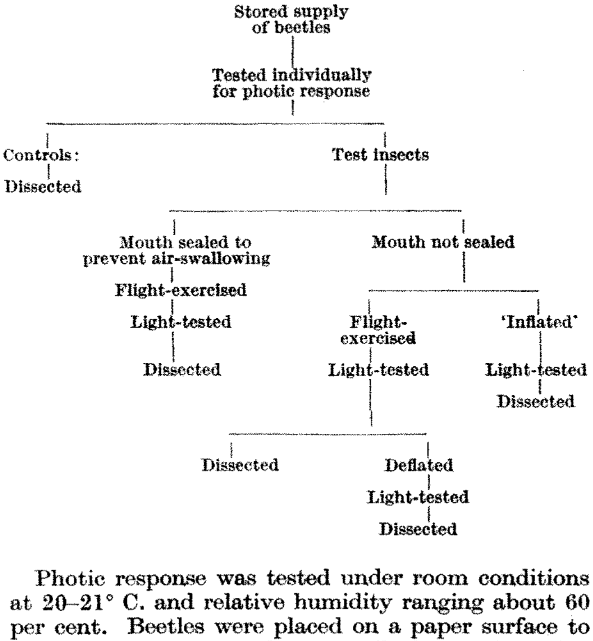
A previous communication[1] reported the effectiveness of flight exercise in abolishing the overruling response to light in overwintered adults of the ambrosia beetle *Trypodendron* (*Xyloterus*) *lineatum* Olivier. This observation is ecologically significant in explaining the behaviour of the insect in terms of one of its normal experiences. Evidently the photopositive response which initially compels it, advantageously, to dispersive flight indirectly sponsors termination of flight and unmasks a latent responsiveness to host factors, allowing it to settle down.

The change seemed to occur only after a period of flight, never in its absence. Nevertheless, belief in the role of flight could be strengthened if a possible mechanism could be demonstrated. Furthermore, a demonstrable mechanism might aid in the interpretation of anomalous behaviour in other work with this insect, or be used for experimental purposes.

Some of the more obvious facts, drawn from existing knowledge, were brought to bear on the question. Chapman[2] had reported, for the same species, that the ventriculus, and often the œsophagus, of beetles taken in flight are distended by a large gas bubble. The significance of the discovery was not clear at the time.

The coincidence of the two phenomena, namely, photic reversal and gas accumulation, associated with a common experience, namely, flight, could not be ignored, but how could gas in the alimentary tract be assumed to affect behaviour ? The first and simplest possibility was that it exerts pressure and creates a signal that is relayed to the central nervous system. Photic reversal associated with pressure in the body of spruce budworm larvæ had been observed by Wellington[3]. The reversal occurred regardless of how the pressure was applied, whether from food, injected fluid or externally applied pressure of a ligature. The influence of pressure is relayed to the higher neural centres through the 5th abdominal ganglion, which can be 'blocked' by local anæsthetizing with methylal (dimethoxymethane).

A schedule of tests was drawn up to compare responses of *Trypodendron* after various treatments contrived to introduce gas pressure.



Photic response was tested under room conditions at 20–21° C. and relative humidity ranging about 60 per cent. Beetles were placed on a paper surface to observe and trace with a pencil their orientation towards a window source of light. Each beetle was given five trials beginning each time from a different direction of point relative to the light.

Beetles of both sexes fresh from overwintering, and thus non-flown, were photopositive in varying degrees. The rate of turn towards light, rate of crawling, and frequency of attempts to fly varied with individuals. Some individuals took short (5–10 cm.) backward flights before taking the typical laterally oscillating course, which advanced them at about 2 m./sec.

Unflown beetles generally had no gas bubble in the ventriculus, and rarely had a small one.

Beetles with a viscous seal over the mouth did not change behaviour after flight, and dissection revealed no gas bubble.

Beetles suspended by the pronotum responded variously to the opportunity for anchored flight, some maintaining almost uninterrupted wing movement for hours, others being intermittent, and still others 'flew' only occasionally. Prolonged flight was generally followed by a decisive reversal of photic response, and distension of the gut with gas was always associated with photic reversal. Deflation by piercing through the elytra and soft dorsum into the alimentary tract with a finely drawn glass capillary (when not accompanied by surgical damage and paralysis) restored the photically reversed beetles to light-positive behaviour.

Unflown beetles, artificially inflated by blowing through a fine drawn capillary sealed to the mouth of the beetle with heavy grease, became photically reversed. Dissection confirmed the successful inflation.

The evidence is thus : that the unflown beetles are strongly photopositive ; that through prolonged flight, but not without it, they become indifferent or negative to light ; that accumulation of gas in the gut accompanies the change, and the change is always associated with the gas ; that deflation restores the photopositive response ; and that artificial inflation is effective in abolishing the photopositive response.

The evidence is thus reasonably conclusive that the release of responses other than photic in *Trypodendron* is brought about by air swallowed during flight, acting presumably by its pressure.

MICROBIOLOGY

Oxygen Inhibition of Respiration in *Azotobacter*

THE effect of oxygen partial pressure on *Azotobacter* has been studied by Meyerhof and Burk[1], Burk[2] and by Parker and Scutt[3], with essentially similar findings. Respiration in this organism reaches a clearly defined maximum at 0·15–0·30 atm. oxygen, Burk's results tending to the lower values and Parker and Scutt's to the higher. Respiration was measured with either sucrose or glucose as the substrate, and a similar observation was made by Tschapek and Giambiagi[4], who followed glucose dissimilation rather than oxygen uptake. Inhibition of some enzyme system(s) in the respiratory mechanism appears to be the most likely explanation of this effect.

The oxygen effect seems to be peculiar to *Azotobacter*, since we were unable to find such a well-defined inhibition when the respiration of *Bacillus subtilis* (N.C.T.C. 518), *Saccharomyces cerevisiae* and *Rhizobium trifolii* (Australian strain *NA* 30) was measured on sucrose as substrate under different oxygen partial pressures ranging from 0·05 atm. to 1·00 atm. oxygen (Fig. 1).

An attempt has been made to identify a stage sensitive to oxygen of the respiratory system using various substrates as the carbon source and testing for the presence of the inhibition.

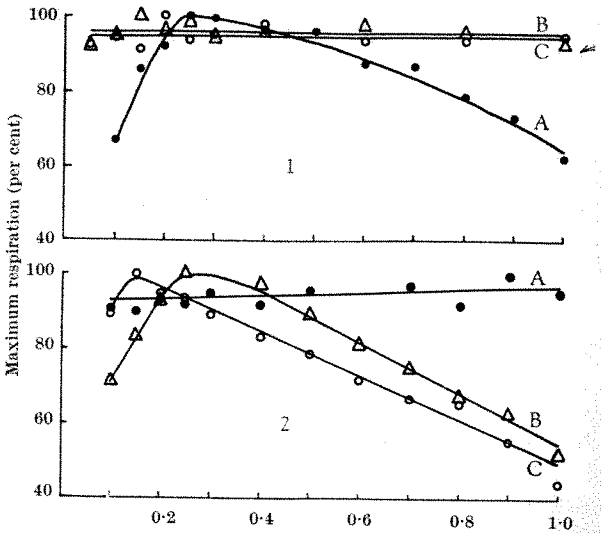

Fig. 1. Plot of oxygen uptake against oxygen partial pressure for three different organisms. Values indicate the percentage of the maximum uptake observed. Curve *A*, *Azotobacter vinelandii*, strain Wisconsin *O*. Curve *B*, *Rhizobium trifolii*, strain *NA* 30. Curve *C*, *Bacillus subtilis*, N.C.T.C. 518

Fig. 2. Plot of oxygen uptake against oxygen partial pressure for *Azotobacter vinelandii* on different substrates. Curve *A*, glycerol. Curve *B*, pyruvate. Curve *C*, succinate

Cells of *A. vinelandii* (strain *O*, kindly supplied by Prof. P. W. Wilson) were grown overnight on synthetic media, using sucrose and urea as the carbon and nitrogen sources, respectively. The cells were recovered by centrifugation, re-suspended in a complete mineral salts medium containing the desired carbon source, and aerated for 4 hr. in the presence of urea as a source of nitrogen. This period sufficed for adaptation of the cells[5]. Oxygen uptake was then measured by the conventional Warburg technique in short-term experiments ($\frac{3}{4}$ hr.), using a known density of organisms under oxygen–argon mixtures containing 0·1–1·0 atm. oxygen.

Comparable results to those given with sucrose were found for glucose, pyruvate, acetate, succinate and malate, although the inhibition was more severe with the organic acids than with the sugars. Sample curves for three of these substrates are shown in Fig. 2. Glycerol is the obvious exception, no inhibitory effects of oxygen being detectable in this case.

Addition of —SH group stabilizing reagents (cysteine, glutathione) at concentrations up to 0·01 *M* failed to protect the organisms from the toxic effects of oxygen. That they are permeable to cysteine was shown by the toxic effect of the higher levels of cysteine used.

The failure of the organic acids to 'short-circuit' the inhibition suggests that the oxygen-sensitive system must be external to glycolysis, lying either in a tricarboxylic acid cycle known for these organisms[6], or in the terminal respiratory pathway. Inhibition by oxygen in the former cycle has been reported for pyruvic acid oxidation in *Staphylococcus aureus*[7] and rat brain[8], and for a step in the reactions between citrate and α-oxoglutarate in potato tubers[9]. Oxygen inhibition of an enzyme in the latter pathway has been shown recently for cytochrome *c* reductase[10].

It is postulated that the pattern seen in Fig. 1 for *A. vinelandii* occurs as a result of two opposing systems : (*a*) a terminal oxidation system which reaches a maximum value about 0·25 atm. oxygen and then maintains this value at least up to 1·0 atm.; and (*b*) an oxygen-sensitive system the inactivation of which increases with increasing partial pressure of oxygen and which determines whether the potential activity of system (*a*) is reached.

The rising part of the experimental curve could then be explained as a rapid rise in the activity of (*a*) compared to which inactivation of (*b*) is negligible. At higher partial pressure of oxygen, the declining activity is due to inactivation of (*b*).

Examples known for system (*b*) have already been mentioned. A cytochrome oxidase system with characteristics of system (*a*) is known from *Pseudomonas*[11].

We are unable to offer an explanation of the apparent lack of inhibitory effect when glycerol is used as the substrate. It suggests the possibility that a permease system is being poisoned, but this seems unlikely as the oxygen effect is similar with substrates of neutral sugars or anionic organic acids. Further work on oxygen poisoning is in progress.

A Micro-method for performing the Phenylalanine Test on Cultures from Multi-carbohydrate Media

THE phenylalanine test is of great value for investigating cultures of organisms in the family Enterobacteriaceae. Organisms in the *Proteus* group are able to de-aminate the amino-acid, phenylalanine, to form phenylpyruvic acid, whereas members of the other groups in the family are unable to do so. Buttiaux *et al.*[1] claim that this test is more reliable than the urease test for the identification of *Proteus* strains.

In a previous communication[2] a technique was described in which the bacterial growth from Kligler's iron agar, or other multiple carbohydrate media, could be tested for its ability to de-aminate phenylalanine. Although this technique gives reliable results, it has several disadvantages: (1) the removal of the cells from the Kligler's iron agar slope by washing with phenylalanine solution leaves no cells for further biochemical or serological examination; (2) a shaker and bijou bottles (which need to be sterilized and cleaned before re-use) are needed; (3) it is time-consuming to test a large number of cultures; (4) the cost of the phenylalanine reagent and of the glassware preparation is not inconsiderable.

With these points in mind, a much simpler technique was evolved, whereby the original bacterial culture on Kligler's medium was retained, neither a shaker nor bijou bottles were required and the cost of performing the test was reduced by more than 90 per cent.

In the micro-method now proposed, ordinary 3 in. × 1 in. glass slides have six squares ($\frac{3}{8}$ in. × $\frac{3}{8}$ in. or 1 cm. × 1 cm.) etched on to them on one side, with a diamond glass cutter. The slides are then warmed in a bunsen burner flame, and a black wax pencil is rubbed along the etched lines, leaving these clearly marked in black, when the excess wax is rubbed off with a soft cloth.

From a Pasteur pipette, 1 drop of a 0·4 per cent β,L-phenylalanine solution prepared in 0·01 *M* phosphate buffer at *p*H 7·4 is placed in the centre of each of the etched squares on the slides. A heavy inoculum of bacterial culture is removed from the slope of the Kligler's medium, using a loop, and this growth is emulsified in one of the drops of phenylalanine. This is best done holding the slide against a black background, as it is essential to obtain as heavy a cell suspension as possible. The waxed, etched lines prevent the drop from spreading beyond its square (Fig. 1).

The slide is now placed on a circle of damp filter paper in the bottom of a Petri dish, and, after the cover has been replaced, the assembly placed for 20 min. at 37° C. in an incubator. At the end of this period, 1 drop of an 8 per cent ferric chloride solution (aqueous) is added to each of the drops of bacterial suspension on the slide, and the Petri dish is tapped gently on the side to aid the mixing of the drops. An immediate dark green colour develops if phenylpyruvic acid has been formed. This green colour fades within a minute, therefore the reactions should be noted at once.

In a comparison made between this micro-method and the method previously described[2], thirty cultures

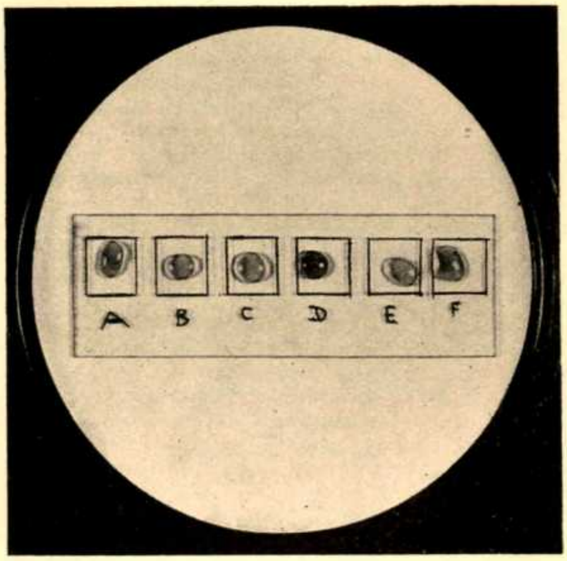

Fig. 1. Slide showing etched, waxed squares, and phenylalanine tests with cultures marked *A*, *B*, *C*, *D*, *E* and *F*. Only *D* is showing a positive reaction

of organisms in the Enterobacteriaceae, including twenty *Proteus* strains, were inoculated on to Kligler's iron agar, incubated for 18–24 hr. at 37° C., and both methods of performing the phenylalanine test were used on the bacterial growth from the slopes. In all cases the micro-method gave the same results as the other method; all the *Proteus* strains were strongly positive, all the other strains were negative (yielding yellow or brown colorations).

Similarly, using another multiple carbohydrate medium: phenol red agar base (Difco) 3·1 per cent, lactose 1 per cent, sucrose 1 per cent and mannitol 0·1 per cent, identical results were obtained.

After completing the micro-test, the slides may be placed in a disinfectant solution until required again, when all they need is to be rinsed with running water and dried.

This simple micro-technique would seem to allow the rapid examination of large numbers of cultures such as might be encountered in the routine and in the research laboratory.

Absence of Lysogeny in *Pasteurella pestis*

A survey of the literature suggests that most bacteria are lysogenic for one or more phages. This communication reports failure to detect or establish lysogeny among strains of *Pasteurella pestis*. The object of the work was to obtain a temperate phage suitable for genetic study by means of transduction[1] of factors determining virulence in this organism[2]. Fifty-four different strains of *P. pestis* (Table 1) were screened for lysogeny and attempts were made to establish lysogeny with phages lytic for *P. pestis*.

In the screening experiments, a method based on that of Fisk[3] was used. Each of the 54 strains was tested both for lysogeny and as a potential phage indicator. Organisms derived from overnight cultures in tryptic digest meat broth grown at 28° C. in gently rotated tubes were used throughout. Indicator plates were prepared by spreading about 2×10^{8} organisms as lawns on broth agar plates containing 0·075 per cent sodium metabisulphite and dried. Approximately 0·01-ml. drops of each culture were applied to each lawn using a multiple inoculator[4]. The plates were examined after incubation for 40 hr. at 28° C. No evidence of lysogeny was seen. Known lysogenic strains of *Salmonella typhimurium* gave clear evidence of their lysogeny when tested by this method, using a suitable indicator strain.

Ultra-violet induction was attempted by irradiation of cultures of each strain in phosphate buffer at 9 ergs/mm.^{2}/sec. for 20 sec. using a Hanovia low-pressure lamp. None showed a reduction in turbidity on subsequent incubation in broth at 28° C. over a 10-hr. period. No phage activity was detected when drops of these cultures were plated on lawns of the 54 strains of *P. pestis*, 5 strains of *P. septica*, 5 of *P. haemolytica* or 6 of *P. pseudotuberculosis*.

In case failure to detect lysogeny had been due to the spontaneous liberation of small numbers of phage particles only by a strain of *P. pestis*, two mixed cultures consisting of about 5×10^{7} organisms of all strains were shaken at 28° C. and 37° C. respectively for 6 hr. to permit such phage, if present, to propagate on a sensitive strain and so increase the chance of its detection. The mixed cultures were centrifuged and the supernatants sterilized with chloroform. None of the *P. pestis* strains was lysed by these culture fluids. Since it was possible that strains of *P. pestis* failed to act as indicators because they were all lysogenic for the same or related phage, attempts were made to 'cure' a strain by repeated heavy ultra-violet irradiation[5]. However, derivatives of strains of *TS* which had been subjected to one, two, three or four serial irradiations in buffer at 11 ergs/mm.^{2}/sec. for 3 min. used as potential phage indicators also failed to reveal phage in the same culture fluids.

Of 17 phages which were lytic for strains of *P. pestis* at 28° C. or 37° C. on sodium metabisulphite medium (8 isolated from local sewage and 9 donated preparations) one, *P*1*k* (ref. 6), gave completely turbid plaques and three others plaques with wide turbid edges. Isolates from the former gave only non-lysogenic colonies resistant to *P*1*k*: those from the latter gave sensitive bacteria and virulent phage which could apparently be 'carried' through at least one single-colony isolation. Microcolonies appearing on lysed lawns of *P. pestis* strains after incubation for 5–7 days at 28° C. followed by 14 days at room temperature also yielded only sensitive bacteria and 'carried' phage. On the basis of host range and efficiency of plating, at least 7 of the 17 phages appeared to be different. Had any of them arisen from the same temperate phage by different mutations to virulence, multiple infection with pairs of them could have resulted in the establishment of lysogeny[7]. This was attempted by inoculating separate lawns of strain *TS* on sodium metabisulphite medium infected with each of 15 of the phages with drops of suspensions of each of them using the multiple inoculator. The multiplicity of infection for both phages within each area covered by a drop was greater than one and the whole process took only 25 min. On prolonged incubation only slow-growing microcolonies appeared which were again shown to consist of sensitive bacteria and virulent phage.

If any strains of *P. pestis* are lysogenic they, or suitable indicator strains, or both, are rare. There are a few reports of failure to detect lysogeny in other species of bacteria[8]. Of these, only Williams Smith's failure to detect it among 62 strains of *Salmonella pullorum* involved experiments on a similar scale to those with *P. pestis*. It is possible that all *P. pestis* strains tested are lysogenic for the same non-inducible phage. The occurrence of colonies comprising sensitive *P. pestis* organisms and virulent phage is thought to be a further example of 'pseudolysogeny'[9], although less stable than that previously reported for this organism[10].

I am indebted to Dr. R. Devignat of Elisabethville, Congo, for strains of *P. pestis*, and Drs. N. Boulgakov, G. Girard and F. Jacob, of Paris, and Dr. D. Eisler, of California, for phage preparations. Discussion with Dr. T. W. Burrows and the technical assistance of Miss R. M. King are gratefully acknowledged.

GENETICS

Effect of Hybridization on the Primary Polydipsic Trait of an Inbred Strain of Mice

A non-obligatory polydipsia which is reflected in the excretion of large quantities of urine of low specific gravity has been found in more than 90 per cent of an inbred strain of mice (*STR/N*)[1–3]. It appears to be due to an innate thirst, the satisfaction of which is entirely unnecessary for survival. It is present in mild degree at the earliest ages studied (4 weeks), and is greatly accentuated at about 6 months of age. There is an associated high mortality in males due to the combined presence of polyuria and a urethral plug. The latter was found in almost all male mice of all strains examined, and is probably derived from seminal fluid.

To attempt to obtain information on the mode of inheritance of the trait, the intake of water and urine specific gravity[4] of F_1 and F_2 hybrids resulting from the mating of the inbred polydipsic strain and a non-polydipsic strain and back-crosses were studied at 1–5 months of age in a total of 250 animals. The mean urine specific gravities and intake of water of the hybrid mice tended to be intermediate between those for the polydipsic and non-polydipsic strains, but resembled much more closely the non-polydipsic strain values (Table 1). There was no consistent difference between F_1 and F_2 hybrids. For reasons which are not apparent, back-crosses with both polydipsic and non-polydipsic strains tended to resemble the polydipsic strain. The inheritance of the trait does not appear to be as a simple recessive. The precise mode of inheritance and the number of genes involved will require examination of considerably larger numbers of animals.

Chromosome Rearrangements induced by X-Rays in Immature Germ Cells of *Drosophila*

Many investigations have indicated that few chromosomal aberrations or losses have been produced in the immature germ cells of *Drosophila*[1–3]. The present work deals with factors influencing the production of chromosome rearrangements by X-rays in early oocytes and oogonia of *Drosophila melanogaster*.

Attached-*X* females aged 2–3½ and 8–9½ days of the genetic constitution $sc\ ct^n\ oc\ car.y\ In\ 49\ sn$ and an $sc^{V1}.Y^S$ chromosome were irradiated with 2,400 r. X-rays. The dose was given either in 2 min. or in two 1-min. fractions separated by an hour interval in air (*AAA*); or in two 1-min. fractions separated by an hour interval with a 53-minute nitrogen flushing of the flies (*ANA*). After treatment the females were mated with $y\ sc^{S1}\ B\ f\ In\ 49\ v$ males and periodically transferred for 32 days. The progeny were scored for detachments of the attached-*X*. Detachments involve translocations between the *X* and one of the following: the *Y*, the IVth or the major autosomes[4,5].

* *AAA* = air present during irradiations and air present during 1 hr. interval.

† *ANA* = air present during irradiations and nitrogen present during 53 min. of 1 hr. interval.

The results are presented in Table 1. The frequencies of detachments in all treatments are presented as the observed exceptions relative to the total number of females. The frequency of occurrence of detachments is more complex due to non-random disjunction and different viabilities of the sexes, to mention just two factors. Rearrangements have been obtained from every treatment and sample of germ cells. In young females fractionation of treatment results in significantly fewer rearrangements ($P < 0\cdot01$) than the concentrated treatment. Anoxia during the interval results in significantly higher rearrangement frequencies ($P < 0\cdot001$) than the uninterrupted treatment.

In old females there appears to be no fractionation effect, which is, unexpectedly, the same as the results obtained in eggs laid shortly after irradiation, but the *ANA* series does not show the expected increase in rearrangements. The results for eggs laid 11–32 days are substantially in agreement with the results obtained for rearrangements produced in eggs laid 0–4 days after irradiation[6]. For purposes of comparison, a portion of the 0–4 days results are reproduced in Table 1.

The results for immature oocytes and oogonia are consistent with the notion that, for young females, these rearrangements are formed completely very shortly after irradiation, and show that they depend on oxygen for completion, and that anoxia blocks restitution and usually alters the relationship of rejoining. Furthermore, the results indicate that the age of the female at irradiation appears to influence the restitution process in her various germinal cells.

Genetic analyses demonstrated that detachments of the attached-*X* chromosomes were indeed in many cases translocations involving the major autosomes as well as the *Y* and the smaller IVth chromosome of *Drosophila*[4,5]. Other workers, for example Neuhaus[7], considered the induced detachments to be cross-overs between the *X* and *Y*.

Induced 'crossing-over' is confined to heterochromatic regions[8]. Detachments also occur there. Induced 'cross-overs' are greater in frequency in eggs laid during 6–15 days after irradiation than days 0–4. In the case of detachments more of the changes are found in eggs oviposited in the first days, as is also the case for other induced mutational events, for example, recessive lethals, dominant lethals and chromosome loss[3].

The notable dearth of chromosome translocations found induced in early oocytes and oogonia, as well as in spermatogonia, is partly due to the sorting out, in perhaps half the cases, of complementary parts of the rearrangement into different daughter cells (including a mechanism suggested by Novitski[1] that oogonial sex cells lacking an *X* chromosome may be unable to survive and do not reach the meiotic stage); but it has long been known that this loss of cases is far from enough to explain the lack of translocations obtained from these stages. The present results show that separation of the attached-*X* does not necessarily cause a lethal aneuploidy, and would permit the survival of those cells in which the detachment is rearranged in a euploid order.

The frequencies of gross chromosome rearrangements (if we may so consider them) reported here for immature germ cells in females are the highest observed, but the genetic technique is more sensitive than those used by previous workers.

This research was supported by grants from the National Science Foundation and the Rutgers University Research Council.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Experimental Officer (with a degree in science or horticulture, or equivalent qualification) in the Physiology Section, for growth and development studies on vegetable crops—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (August 5).

Scientific Officer (with a good honours degree in chemistry, or equivalent qualification, and preferably with some experience of, and interest in, food technology), for investigations into the problems involved in various aspects of biscuit manufacture—The Deputy Director of Research, Baking Industries Research Station, Chorleywood, Herts (August 5).

Lecturer or Assistant Lecturer in Zoology (Entomology) at the University College of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 7).

Experimental Officer (graduate in agriculture, botany or agricultural botany) in the Cereal and Brassica Breeding Station, for work on the recording and handling of breeding and genetical material—The Secretary, Welsh Plant Breeding Station, Plas Gogerddan, Aberystwyth (August 10).

Lecturer (preferably with research experience in surface chemistry or chemical kinetics) in Pharmacy at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 11).

Lecturer/Senior Lecturer in Classical Archæology at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, August 11).

Lecturer (graduate in science or engineering) in the Department of Building Science—The Registrar, The University, Liverpool (August 12).

Senior Research Assistant (Ph.D. in theoretical physics or equivalent research qualifications) to Prof. N. H. March, Department of Physics, for work concerned with the study of impurities and imperfections in metals and semi-conductors using density matrix methods—The Registrar, The University, Sheffield 10 (August 12).

Fellow (specialized in organic chemistry, with special reference to the chemistry of compounds of neuropharmacological significance) in the Department of Physiology, John Curtin School of Medical Research, Australian National University—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (August 14).

Lecturer or Assistant Lecturer (with special interest in physical chemistry) in Chemistry at the University College of the West Indies—Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 14).

Lecturer or Assistant Lecturer (preferably with a knowledge of tropical soils) in Soil Science in the Faculty of Agriculture, University College of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 14).

Research Assistant (with a degree in chemistry, biochemistry, agricultural chemistry or a related subject) in the Department of Physiological Chemistry, for a research programme supported by the Agricultural Research Council on bone metabolism and egg shell formation in the fowl—The Professor of Physiological Chemistry, The University, Reading (August 14).

Lecturer (with a higher degree in science with specialization in some branch of physical chemistry, with evidence of research ability and preferably with university teaching experience) in Physical Chemistry at the University of Queensland—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (August 15).

Research Assistants (2) (with at least a B.Sc. degree, or equivalent qualification, and with special interest in physical chemistry or chemical engineering), to continue a study of the equilibrium properties of imperfect gases—The Registrar (Room 22, O.R.B.), The University, Reading, Berks (August 15).

Senior Lecturer or Lecturer (preferably with research interests in epidemiological or immunological aspects) in Parasitology in the Faculty of Rural Science, University of New England, Armidale, New South Wales, Australia, to teach and carry out research in parasitology with particular reference to livestock aspects—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 15).

Textile Technologist (with a first- or second-class honours degree in textile technology, chemistry or physics, or Associate or Fellow of the Textile Institute, or equivalent qualifications) at the Tropical Products Institute, London, to supervise a group concerned with research into, and laboratory examination of, various aspects of animal and vegetable fibres, pulp, paper and board-making materials, hides, skins, etc., of tropical origin—Civil Service Commission, 17 North Audley Street, London, W.1, quoting Ref. No. S/5333/61 (August 15).

Lecturer or Assistant Lecturer in the Department of Anatomy—The Registrar, University College, Cathays Park, Cardiff (August 18).

Assistant Lecturer in Physiology—The Registrar, The University, Sheffield (August 19).

Chair of Pathology in Makerere University College, East Africa—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 20).

Lecturer or Assistant Lecturer (with experience and research interests in plant physiology) in Botany at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 20).

Reader in Electric Traction at Imperial College—The Academic Registrar, University of London, Senate House, London, W.C.1 (August 21).

Senior Lecturer or Lecturer (with a thorough knowledge of comparative and general physiology) in Zoology at the University of Cape Town, South Africa—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, August 21).

Fellow (Rees Jefreys Road Fund) (with an honours degree in mathematics, geography or town planning, or equivalent qualification) at the Road Research Laboratory, Traffic and Safety Division, Langley, Bucks, to work either on the quantitative aspects of urban transport needs or traffic conditions in new towns—The Director of Road Research, Road Research Laboratory, Harmondsworth, Middlesex (August 25).

Reader in Aeronautics at Imperial College—The Academic Registrar, University of London, Senate House, London, W.C.1 (August 29).

Lecturer or Senior Lecturer in Botany at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 30).

Keeper of Scientific Books (with considerable experience of university or research library administration and a good honours degree, preferably in science), to superintend the Radcliffe Science Library—The Librarian, Bodleian Library, Oxford (August 31).

Lecturer (with an honours or higher degree in chemical engineering or equivalent qualifications, and preferably with an interest in mass transfer or nuclear chemical engineering) in Chemical Engineering at the University of Canterbury, New Zealand—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, August 31).

Lecturer or Assistant Lecturer (preferably with qualifications in inorganic chemistry) in the Department of Chemistry—The Secretary, Chemistry Department, University College, Science Buildings, Merrion Street, Dublin (August 31).

Lecturer in Crop Ecology at the Waite Agricultural Research Institute, University of Adelaide, South Australia, to undertake ecological or physiological studies on the lucerne crop, and to evaluate and develop lucerne ecotypes for grazing—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (August 31).

Lecturer (with a degree, preferably an honours degree and some industrial and teaching experience) in Mechanical Engineering at the University of Queensland, to conduct lectures, laboratory and drawing office work in the fields of applied mechanics (including dynamics and stress analysis) and engineering drawing and design—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (August 31).

Reader (with special interest in the properties of materials and able to initiate and guide research into the properties of materials such as are related to future developments in electrical engineering) in Electrical Engineering at Imperial College—The Academic Registrar, University of London, Senate House, London, W.C.1 (August 31).

Scientific Officer (honours graduate with a special interest in plant breeding and genetics), for work on tree fruits under experienced leadership, as one of a team of fruit breeders—The Secretary, East Malling Research Station, Maidstone, Kent (August 31).

Senior Lecturer or Lecturer (male, British, with an appropriate honours degree) in Physics and Electrical Engineering at the Royal Naval College, Greenwich, London, S.E.10—The Director (P), Education Department, Admiralty, London, S.W.1 (August 31).

Technical Officer or Senior Technical Assistant (with considerable laboratory experience and competence with apparatus and techniques in biology, and preferably with the preparation and collection of botanical teaching materials and histological methods) at the University of Adelaide, South Australia, to supervise basic laboratory apparatus and preparation of undergraduate classes—The Registrar, The University of Adelaide, Adelaide, South Australia (August 31).

Assistant Lecturer in Mathematics (Pure or Applied)—The Principal, Royal Holloway College, Englefield Green, Surrey (September 1).

Lecturer in the Department of Medical Physics—The Secretary, Royal Free Hospital School of Medicine, 8 Hunter Street, London, W.C.1 (September 1).

Senior Lecturer in Applied Electronics at Victoria University of Wellington, New Zealand—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, September 1).

Lecturer or Assistant Lecturer (medically or non-medically qualified candidate) in the Department of Histology—The Registrar, The University, Liverpool, quoting Ref. CV/N (September 4).

Lecturer or Junior Lecturer in Pure Mathematics—The Registrar, Trinity College, Dublin (September 4).

Lecturer (with experience of modern physical methods of structure determination, and especially of those involving electric birefringence, dipole moments, etc.) in Physical-Organic Chemistry at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 8).

Lecturer in Social Anthropology at the University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, September 8).

Assistant Director of the British Institute of History and Archæology, Dar es Salaam, Tanganyika, to combine research with the supervision of the Institute's library and to share in the direction of students—Secretary, British Institute of History and Archæology in East Africa, c/o British Academy, Burlington Gardens, London, W.1 (September 15).

Chair of Philosophy in the University of Ceylon—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (Ceylon and London, September 15).

Lecturer or Assistant Lecturer in Parasitology (Medical Entomology) at the University of Malaya, Singapore—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (September 15).

READER or SENIOR LECTURER IN AGRICULTURAL CHEMISTRY; LECTURER IN AGRICULTURAL CHEMISTRY; and a LECTURER IN ANIMAL HUSBANDRY in the Faculty of Agriculture, Makerere University College, East Africa—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (September 15).

SENIOR LECTURER or LECTURER (well qualified in electrical engineering or physics, with general experience in electronics and a considerable detailed knowledge of solid-state devices and circuits) IN ELECTRICAL ENGINEERING at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (September 15).

CHAIR OF STATISTICS tenable in the Newcastle Division of the University—The Registrar, Durham University Office, 1A Kensington Terrace, Newcastle-upon-Tyne 2 (September 25).

HISTOCHEMIST, Scientific Officer grade (with a first- or good second-class honours degree and preferably with some research experience in a related field), for research into mechanisms of insecticidal action using histochemical methods—The Director, Pest Infestation Laboratory, London Road, Slough, Bucks (September 30).

SCIENTIFIC OFFICER (honours graduate), for research on problems arising out of the vegetative propagation of fruit plants—The Secretary, East Malling Research Station, Maidstone, Kent (September 30).

SENIOR LECTURER IN PHYSICS at Victoria University of Wellington, New Zealand—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, September 30).

ASSISTANT, Grade B (qualified to teach to G.C.E. advanced level), IN BIOLOGY—The Principal, Percival Whitley College of Further Education, Francis Street, Halifax.

ASSISTANT, Grade B, IN THE DEPARTMENT OF PHYSICS—The Principal, College of Technology, Huddersfield.

ASSISTANT EXPERIMENTAL OFFICER or EXPERIMENTAL OFFICER (with previous experience in virological techniques, preferably including tissue culture), for work connected with production of attenuated strains of foot-and-mouth disease vaccines—The Secretary, Research Institute (Animal Virus Diseases), Pirbright, Surrey.

ASSISTANT EXPERIMENTAL OFFICER (with a pass degree in physics or physical chemistry or H.N.C., or equivalent qualification), to work on physical problems on the processing of foodstuffs—The Director, Low Temperature Research Station, Downing Street, Cambridge.

BIOCHEMIST or BIOCHEMICAL ASSISTANT, to assist with metabolic research—The Director, Medical Unit, King's College Hospital Medical School, Denmark Hill, London, S.E.5.

CHEMIST (with research experience in physical or bio-chemistry), to work on certain aspects of the chemistry of wheat protein—The Director of Research, Cereals Research Station, Old London Road, St. Albans, Herts.

LECTURER (preferably with a higher degree and industrial research experience) IN METALLURGY in the Department of Materials, to lecture at postgraduate level in his own special subjects; to supervise student research work, and to assist in initiating and directing long-term programmes of research, some of which may be externally sponsored—The Recorder, College of Aeronautics, Cranfield, Bletchley, Bucks.

METALLURGIST, Scientific Officer grade (with an honours degree), at the Royal Mint, to assist in supervision of production, investigation of problems of materials and manufacture, assaying and general research in the fields of physical metallurgy and metallography—Establishment Officer, Royal Mint, London, E.C.3.

POSTDOCTORAL RESEARCH FELLOW IN THE THEORETICAL PHYSICS INSTITUTE—L. E. H. Trainor, Physics Department, University of Alberta, Edmonton, Alberta, Canada.

RESEARCH ASSISTANT (preferably with experience in cytology), to take part in a programme designed to study human chromosome abnormalities and associated disorders—The Secretary, Genetics Department, The University, Sheffield 10.

RESEARCH ASSISTANT (graduate in physics, with research or industrial experience) IN LOW-TEMPERATURE PHYSICS, to work under the direction of Dr. Yates, on the determination of the thermal constants of materials at liquid-hydrogen temperatures—The Registrar, Bradford Institute of Technology, Bradford 7.

RESEARCH ASSISTANT (recent graduate in physics) IN THE DEPARTMENT OF PHYSICS, for work on track analysis in connexion with the National Bubble Chambers project—The Assistant Registrar (Science), The University, Edgbaston, Birmingham 15.

SENIOR LECTURER (with a good honours degree and appropriate teaching and/or industrial experience) IN HIGH POLYMER CHEMISTRY—The Principal, Rutherford College of Technology, Northumberland Road, Newcastle-upon-Tyne 1.

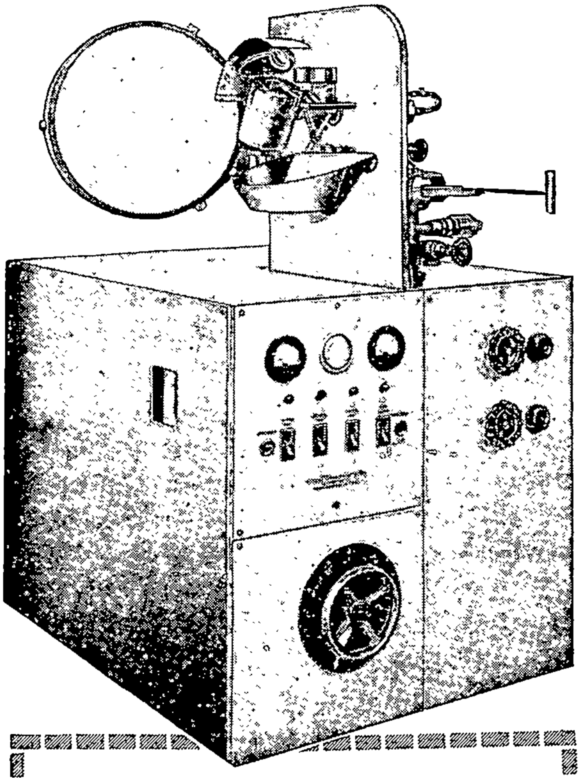
WILD BARFIELD NRC*

Laboratory Vacuum Furnace



Model 2904

2 lb. to 8 lb. capacity

(FOR OPERATION UP TO 2,000°C)

Made in Britain to the designs of the National Research Corporation of Mass., U.S.A. who have built more high vacuum furnaces now in successful operation than any other firm in the world. The Model 2904 Vacuum Furnace is a self-contained unit for high-temperature operation at high vacuum or under controlled atmosphere. It is heated by a tungsten resistance heating element with molybdenum heat shields in a water-cooled stainless steel sleeve.

This permits:

- Close control of temperature
- Good heat distribution
- Long life
- No outgassing or contamination from refractories

FOR MELTING • POURING • SINTERING
ALLOYING • HEAT-TREATING • ANNEALING

Vacuum Arc and Vacuum Induction Furnaces
Vacuum Analysis Equipment • Vacuum Diffusion Pumps

STANDARD EQUIPMENT

- High vacuum pumping system with Wild-Barfield-NRC oil diffusion pump and Gas Ballast mechanical pump.
- Metal cabinet base, overall dimensions 35″ x 43″ x 34″ high.
- Pyrex bell jar, 18″ diameter x 12″ long, protected with a wire mesh guard, or optionally a stainless steel bell jar.
- Water-cooled basin to shield the bell jar and to catch spilled metal.
- Feed-through for thermocouple wires or heater leads for special work.
- 15 kW. power supply, controlled with a variable auto-transformer. Power is supplied to the split tungsten sleeve through water-cooled coaxial leads.

* NRC *is the trade-mark of the National Research Corporation, registered in the United States Patent Office.*

NRC

APPOINTMENTS VACANT

Central Electricity Generating Board

PHYSICS DIVISION

BERKELEY NUCLEAR LABORATORIES

(GLOUCESTERSHIRE)

Applications are invited for posts in these Laboratories. Those appointed will work initially in the following sections, although subsequent transfer between sections will be possible, depending on the developing interests and abilities of the staff concerned.

A. INSTRUMENTATION

For work developing nuclear radiation detectors and other specialized nuclear instruments. Preference will be given to candidates who are capable of devising and developing new techniques of measurement.

B. GRAPHITE

To study the fundamental mechanisms and assess the extent of irradiation damage in graphite and the corresponding changes of physical properties.

C. THEORETICAL PHYSICS

To study various theoretical problems of interest to the Laboratories, including reactor physics and the theory of radiation damage.

● **Initial salaries up to £1,325 per annum are offered in accordance with experience, ability, and qualifications of persons appointed.**

Candidates must have a good honours degree and should be under 26 years of age.

Applications, stating age, qualifications, experience, present position, salary and quoting type of work interested in, to the Appointments Officer, 24/30 Holborn, London, E.C.1, by August 3. Quote Ref. N/317.

NATIONAL INSTITUTE FOR RESEARCH IN DAIRYING

(UNIVERSITY OF READING)

Assistant Experimental Officer required in the Physiology Department to assist with histological investigations related to the endocrine research programme of the department. Applicants should have a pass degree in biology (including zoology), F.I.M.L.T. or equivalent qualifications, and some experience of histological techniques would be an advantage. Starting salary £450 10s. to £740, according to age in scale to £983. Superannuation.

Application form from Secretary, N.I.R.D., Shinfield, Reading. Quote ref. 61/22.

WHESSOE LIMITED

require a

CHEMIST

for Reinforced Plastic Tank Development

Assistant, age 25 to 40, with degree or other recognized qualification, required to join a team working on development of reinforced plastic vessel design and production. His particular responsibility will be to investigate the properties of plastic materials but he will also have the opportunity of taking part in all aspects of this work.

Applications, quoting reference 37/61, and mentioning this paper, should be sent to the Staff Officer, Whessoe Limited, Darlington.

UNIVERSITY OF MANCHESTER

LINEAR ACCELERATOR PROGRAMME

Short-term appointments are available in the Department of Physics of the Faculty of Science for qualified Physicists or Electrical Engineers to assist with the construction and commissioning of a large heavy ion linear accelerator. Experience in one or more of the following fields would be desirable: high vacuum; R.F. techniques (75 Mc./s.); high power rectifier and pulse circuits; general electronic instrumentation and controls. The appointments are for one year in the first instance, and the salary range is £1,000 to £1,500 per annum.

Applications should be addressed to the Assistant Director, Linear Accelerator Laboratory, Physics Department, the University, Manchester 13, from whom further details may be obtained.

ANTARCTICA

GEOLOGIST required by FALKLAND ISLANDS DEPENDENCIES SURVEY for service in the ANTARCTIC for two years. Salary £550 a year with extra allowances for experience and qualifications. Whilst in the Antarctic everything is provided free of charge including clothing, cigarettes etc. Free passages. Liberal leave on full salary.

Candidates should hold a minimum qualification of a first- or upper second-class honours degree in geology and should preferably have specialized in petrology. The person selected will be required to undergo a course of training before leaving the U.K. at the end of the year. While on duty in U.K. an extra allowance of £150 a year is paid before departure and £200 a year on return.

Apply to CROWN AGENTS, 4 Millbank, London, S.W.1, for application form and further particulars, stating age, name, brief details of qualifications and experience and quoting reference M3C/53437/NF.

LONDON COUNTY COUNCIL

NORWOOD TECHNICAL COLLEGE
KNIGHT'S HILL, S.E.27
PHYSICS AND MATHEMATICS DEPARTMENT

(1) Required Lecturer to teach Physics to General Degree and G.C.E. Advanced Level courses. Applicants should have good honours degree, teaching and/or research experience. Salary within the range £1,408 to £1,601.

(2) Two Grade B Assistants to teach (a) Physics and (b) Mathematics. Teaching and/or research experience an advantage. Salary within the range £738 to £1,201 with additions for qualifications and training to a possible maximum of £1,486. Point of entry dependent on experience. These appointments will be temporary in the first instance, but permanency available if satisfactory.

The work in the department comprises principally teaching physics and mathematics to full-time G.C.E. " A " level students, telecommunications courses (C. and G. and Brit.I.R.E.), Sandwich General Degree students, and part-time courses of similar standard.

Application forms obtainable from Principal, and returnable within fourteen days. Enclose self-addressed foolscap envelope. Please quote (FE.3a/N/1926/7).

AUSTRALIA

THE UNIVERSITY OF NEW SOUTH WALES
BROKEN HILL DIVISION
SENIOR LECTURER
MATHEMATICS

The University of New South Wales wishes to appoint a Senior Lecturer in Mathematics to its Broken Hill Division. Applicants should have a higher degree or equivalent qualifications and be interested in promoting and leading research. Salary: £A.2,592 range £A.3,042 per annum. Commencing salary is determined by qualifications and experience. Climatic and disability allowances of £A.104 per annum for a single man, £A.156 for a married man, will also be paid. After passing a medical examination, the successful applicant will be eligible to join the State superannuation scheme. Senior Lecturers may apply for twelve months' study leave on full salary after six years of service. With the approval of the University and its bankers, married men may be assisted by loans to purchase a home. First-class fares to Sydney of appointee and family will be paid. Further details of conditions of appointment may be obtained from the undermentioned.

Four copies of applications, including names of two referees, should be lodged with the Agent-General for New South Wales, 56-57 Strand, London, W.C.2, and a copy forwarded to the Appointments Section, the University of New South Wales, Box 1, Post Office, Kensington, N.S.W., by airmail to reach there before September 8, 1961.

UNIVERSITY OF LEEDS

DEPARTMENT OF ORGANIC CHEMISTRY

Applications are invited for the post of Analyst in the Department of Organic Chemistry. The main duties will be the operation and care of optical equipment including infra-red and nuclear magnetic resonance spectrometers. B.Sc. (Chemistry), and G.R.I.C., or equivalent qualifications desirable. Salary on scale £710 to £1,000 bar to £1,100 with provision for merit award up to £100, according to qualifications and experience.

Apply in writing to Mr. W. A. Wightman, the School of Chemistry, the University, Leeds, 2.

UNIVERSITY OF SHEFFIELD

Applications are invited for a post Junior Research Fellow in Pure Mathematics to begin duties on October 1, 1961. Salary £625 per annum. The appointment will be for one year in the first instance and will be renewable.

Applications (three copies), with the names and addresses of two referees, should reach the Registrar, from whom further particulars may be obtained, by August 19, 1961.

VETERINARY OFFICERS, RESEARCH Officers, Assistant Veterinary Investigation Officers: Ministry of Agriculture, Fisheries and Food. Pensionable posts for men and women aged at least 23. M.R.C.V.S. normally required, and postgraduate experience desirable. Present vacancies for Research Officers in virology, pathology, bacteriology and biochemistry. National salary scales £926 (at 23) to £1,269 (at 32 or over) rising to £1,420, then to £1,778. Promotion prospects.—Write Civil Service Commission, Burlington Gardens, London, W.1, for application form, quoting **130-173-265/61**. Early application advised.

MICROBIOLOGIST OR BIOCHEMIST, recently graduated, required for one year's sponsored research on antibiotics. Salary up to £900 per annum according to experience.—Applications to Dr. J. G. Davis, 9 Gerrard Street, London, W.1.

NEW VETERINARY RESEARCH UNIT DIRECTOR

CIBA is an international chemical undertaking with a world-wide organisation based on substantial research manufacturing and marketing pharmaceuticals, dyestuffs and plastics. In Switzerland and in the U.S.A. CIBA has very well-established pharmaceutical research units and throughout the world a reputation for work of high scientific quality.

It is now proposed to set up veterinary research with the main centre in England. A Director is required for this important development. He will first assist in the design of the new laboratories and build up his team and so bring the new unit to life.

The post will be very well paid by academic standards with pension and other benefits.

Further particulars from Managing Director,

CIBA Laboratories Limited,
Horsham, Sussex.

AUSTRALIA

UNIVERSITY OF NEW SOUTH WALES

The University wishes to appoint Senior Lecturers and Lecturers in the following Faculty:

FACULTY OF SCIENCE

Applied psychology (psychometrics and experimental psychology). Botany. Mathematics, Physics.

Salary: Senior Lecturer, £A.2,586 range £A.3,036 per annum; Lecturer, £A.1,766 range £A.2,471 per annum. Commencing salary is determined by qualifications and experience. Subject to passing medical examination appointees will be eligible to contribute to the State Superannuation Fund. First-class ship fares to Sydney of appointees and family will be paid.

Four copies of applications, including the names of two referees, should be lodged with the Agent-General for New South Wales, 56-57 Strand, London, W.C.2, England, and a copy forwarded to the Appointments Section, The University of New South Wales, Box 1, Post Office, Kensington, N.S.W., Marked SA1.

RADIOCHEMIST

National Physical Laboratory, Teddington, Middlesex, requires a Senior Scientific Officer or Scientific Officer in the Radioactivity Standards group to investigate the optimum chemical composition of radioactive solutions used as standards and to initiate research into the production of thin uniform sources for 4π counting. Opportunities later for investigations using a 3 MeV. Van de Graaff neutron generator for cross-section measurements and the production of radioactive nucleides. Qualifications: first- or second-class honours degree in chemistry or equivalent. At least three years' postgraduate research experience is required for Senior Scientific Officer. Interim salary ranges: Scientific Officer, £773 to £1,267; Senior Scientific Officer, £1,392 to £1,714. Appointments unestablished with possibility of establishment through the Civil Service Commission whilst remaining under 29 (Scientific Officers) and under 32 (Senior Scientific Officers).

Forms from Director, address above, quoting 65ZY.

STATES OF GUERNSEY HORTICULTURAL ADVISORY SERVICE

Applications are invited for the following posts: Plant Pathologist; Horticultural Advisory Officer. Applicants must possess a university degree or equivalent qualification. Final-year students may apply. Both officers will be required to assist in general horticultural advisory work with the emphasis on tomatoes and flower crops under glass, and should be prepared to assist in the development of experimental work. Salaries will be equivalent to the National Agricultural Advisory Service salary scales, starting point according to age and experience.

Applications, giving details of qualifications, experience, relevant personal data, and naming three referees, should be forwarded to the President, States Board of Administration, States Office, P.O. Box No. 43, Guernsey, not later than August 8, 1961. Further particulars can be obtained from the same address.

SK&F

wish to appoint

a

BIOCHEMIST

in their

PHARMACOLOGY DEPARTMENT

The post is newly created and the successful applicant will be responsible for the control of all bio-chemical investigations within the department.

He will be particularly concerned with studies of the actions of new synthetic drugs on metabolic processes with a view to elucidating their mechanisms of action and developing new screening methods for pharmacological activity.

Participation in meetings of scientific societies and publication of results are encouraged.

Previous research experience is essential and the preferred age range is 25-35 years.

An attractive starting salary with annual merit reviews is offered and congenial working conditions in new and well-equipped laboratories will be provided.

Other Company benefits include a non-contributory Pension and Life Assurance Scheme, Staff Cafeteria and an active Sports and Social Club.

Under certain circumstances a married man may be eligible for rented unfurnished accommodation and full payment of removal expenses will be made.

Letters of application, giving fullest possible details considered relevant, should be addressed to:

The Staff Manager,
SMITH KLINE & FRENCH LABORATORIES LTD.,
Mundells, Welwyn Garden City, Herts.
Please quote Reference No. L1491.

Virologist/ Bacteriologist

Extension of activities has created an important senior position in the Vaccine Unit of Pfizer Limited, which is located at Sandwich, Kent.

The post calls for a man generally experienced in biological fields, particularly in the production of bacterial and viral vaccines for human and veterinary use. The man we seek must be a good administrator and able to control and co-ordinate the activities of a large staff engaged in all phases of vaccine operation. He should be qualified to Ph.D. standard, or equivalent, and the preferred age range is 30 to 40.

The appointment will carry an attractive salary, together with other first-class conditions. These include generous non-contributory Pension and Life Assurance Schemes and assistance with housing

Applications are invited: they should be addressed to:

THE CHIEF PERSONNEL OFFICER,
PFIZER LIMITED, SANDWICH, KENT.

THE Pfizer GROUP
CHEMICALS PHARMACEUTICALS VACCINES AGRICULTURAL & VETERINARY PRODUCTS

AUSTRALIA

COMMONWEALTH SCIENTIFIC AND INDUSTRIAL RESEARCH ORGANIZATION

DIVISION OF FISHERIES AND OCEANOGRAPHY

Applications are invited from Honours graduates in Science, or equivalent qualifications, with postgraduate research experience for appointment to the undermentioned positions at the Division's headquarters, the Marine Laboratory located at Cronulla, Sydney, N.S.W.

BACTERIOLOGIST

(No. 320/209)

The present research programme is concerned with fluctuations in the number of marine heterotrophs in the sea and with the cell-wall composition of a marine pseudomonad. These investigations are part of a general project on biological production in Australian waters. Although the appointee would not be required to follow these lines of research he would be expected to initiate research within the very wide framework of the programme on production. Some of this work would be done at sea, and therefore ability to work at sea is an essential requirement for appointment.

Applicants should have postgraduate research experience in bacteriology.

PHYSICAL OCEANOGRAPHER

(No. 320/210)

The present research programme is concerned with studies on circulation, instrumentation, optical properties and fisheries problems, and is carried out in coastal and oceanic waters around Australia, extending into the south-west Pacific Ocean and the south-east Indian Ocean. The appointee could join in these lines of research or could initiate research of his own in theoretical or field problems. Because the appointee would be expected to act as a cruise-leader for some part of each year, ability to work at sea is essential.

Applicants should have postgraduate research experience in oceanography.

Salary: Dependent on qualifications and experience within the ranges £A.1,510 to £A.2,265 per annum or £A.2,395 to £A.2,720 per annum.

Promotion within C.S.I.R.O. is by merit and may ultimately go beyond the upper limit of the scale within which the original appointment is made. By mutual agreement appointment may be for an indefinite period or for a fixed term of three years.

Fares paid, and for a short-term contract return fares paid. Further particulars supplied on application to:

Mr. E. J. Drake, Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2,
to whom applications (quoting relevant Appointment number) should be addressed by October 21, 1961.

PHYSICISTS

required by

UNITED KINGDOM ATOMIC ENERGY AUTHORITY

for the Physics Group of the Fast Reactor Project at the Dounreay Experimental Reactor Establishment.

This Group is primarily concerned with experiments on the Dounreay Fast Reactor (D.F.R.) but its responsibilities go further and many of the experiments are designed to increase our general knowledge of fast reactor physics and, in particular, to anticipate problems concerning the design of future fast reactors.

A wide variety of calculations are made of the neutron flux and energy distributions, for a range of core compositions including possible and actual fuel loadings in D.F.R. The scope of the calculations is wide: they may involve simple methods or, for complex solutions, the use of high-speed computers.

Theoretical methods are developed and applied to the investigation of the dynamic behaviour of fast reactors generally. The transient neutron flux is determined and used to evaluate thermal transients and finally reactivity transients. The response of the fuel, coolant and structure is computed and finally, the overall reactor characteristic.

D.F.R., previously run at only 1 MW, will shortly become the world's highest flux fast reactor, presenting an opportunity to check the accuracy of neutron and gamma shielding calculations, especially for thick shields, and also the effect of the many possible streaming paths for radiation caused by coolant ducts, stepped plugs, etc.

Each of these theoretical programmes is complemented by experiment; e.g., flux distributions are measured in the reactor using fission counters and activation samples. The reactivity oscillator is used to examine the reactor dynamics and this apparatus will require development to improve its accuracy. Special shield plugs incorporating established and recently developed methods for monitoring neutron and gamma fluxes are being constructed.

To support this programme an analogue computer is available and a data link is provided to a "Mercury" computer. Access to a large analogue computer (PACE) and other digital computers is also available.

Appointments will be made, and starting salary assessed, according to age, qualifications and experience within the grade of

SENIOR SCIENTIFIC OFFICER

£1,440 to £1,770

OR SCIENTIFIC OFFICER

£790 to £1,310

Applicants should have at least a second-class honours degree in physics or mathematics, and for the senior grade at least three years approved research experience.

Rented housing or house purchase assistance available for married officers living beyond daily travelling distance.

Hostel accommodation available.

Contributory superannuation.

Send postcard for application form to:

Personnel Manager,
U.K.A.E.A., Reactor Group,
E.R.E., Dounreay,
Thurso, Caithness,
quoting reference 253/34.

Reed
PAPER GROUP

Statisticians

required by the Statistical Applications Unit to take a leading part in the development and application of statistical techniques to Operational Analyses, Experimental Design and Quality Control.

Graduates with several years' experience in these fields are wanted, although new or recent honours graduates in mathematics or statistics will be considered.

We have a turnover of £100 million, factories throughout the United Kingdom, and rapidly expanding interests overseas.

Please write, quoting reference S/SAU/37, to :
The Group Personnel Officer,
Albert E. Reed and Co., Ltd.,
Larkfield, near Maidstone,
Kent.

Ferranti computers

Applications are invited for

SENIOR APPOINTMENTS IN THE FERRANTI ATLAS AND ORION PROJECTS

from

PROGRAMMERS	**ENGINEERS**
SYSTEMS ANALYSTS	**CHEMISTS**
PHYSICISTS	**ECONOMISTS, etc.**

who possess good previous responsible experience in their particular field and correspondingly good academic qualifications.

These appointments will, in all cases, carry salaries fully commensurate with qualifications and experience with the benefit of Staff Pension and Dependants Insurance Schemes.

Applicants should write, giving full details of qualifications and experience (which would be treated in strict confidence) to T. J. Lunt, Staff Manager, Ferranti Limited, Hollinwood, Lancs. Please quote reference BBS.

Walls
ICE CREAM

CHEMIST

If you are under 30, have an honours degree in Chemistry, or equivalent, and would like to apply your knowledge in solving the analytical problems that occur in the expanding ice-cream industry, you are invited to apply for a position in the modern laboratories at Acton.

Previous experience of food analysis will be an advantage. Starting salary will be in accordance with experience, and the conditions are those of a progressive company (in the Unilever Group).

Write, stating age, qualifications and experience to:

The Regional Personnel Manager,
T. Wall & Sons (Ice Cream) Ltd.,
The Friary,
Acton, W.3.

DIRECTOR OF RESEARCH

BRITISH FOOD MANUFACTURING INDUSTRIES RESEARCH ASSOCIATION

LEATHERHEAD, SURREY

The post of Director of Research with The B.F.M.I.R.A. will become vacant on December 1st, 1961. The Association employs a staff of 70 and has modern laboratories situated at Leatherhead. Its activities cover the wide field of pure and applied science in relation to the raw materials of the food industry and their conversion into the finished product.

Scientists who are suitably qualified for directing research work in this field are invited to apply for the post.

The salary will be in the region of £4,000 per annum in accordance with qualifications and experience. A contributory superannuation fund is in operation.

Applications should be addressed to The President, Professor A. C. Frazer, M.D., D.Sc., F.R.C.P., at the Laboratories of The B.F.M.I.R.A., Randalls Road, Leatherhead, Surrey, and should not arrive later than Friday, September 1, 1961.

3M COMPANY

MINNESOTA 3M RESEARCH LIMITED

In connection with the impending building of **New Research Laboratories near London** additional Graduate Chemists, Physicists and non-graduate Technicians will be required. Those who have replied to previous advertisements will be considered for the vacant posts without the necessity of re-application.

In the meantime a number of specialist posts are available with the parent Company in the U.S.A. for the following:

(a) Photographic Emulsion Research Chemists.

(b) Physicist/Engineers with experience in the design of modern photographic emulsion coating plants.

(c) Organic Research Chemists with experience in the synthesis of cyanine dyes.

Employment in the U.S.A. may be on a permanent or temporary basis with the option of return after a few years to the new laboratories in England.

Applications, giving details of age, qualifications and experience, which will be treated in strict confidence, should be made in writing to:

Dr. J. D. Kendall, Managing Director, Minnesota 3M Research Limited, 3M House, Wigmore Street, London, W.1.

APPLICATIONS ARE INVITED FOR THE post of Assistant Librarian. Candidates must have passed at least two parts of the Registration Examination and should preferably have had some industrial or college library experience. Duties will include responsibility for book-ordering, classification, and display work. Hours: 38 per week (including some evening duty during term-time). Salary: APTD I (£645 to £815).—Application forms from the Clerk to the Governors, Mid-Essex Technical College, Market Road, Chelmsford, Essex.

A GRADUATE IS REQUIRED TO PARTICIPATE in biochemical research on coagulation in normal human and human cancer tissue. A suitable candidate could register for a higher degree of the University of Dublin. Stipend from the Sarah Purser Medical Research Fund up to £600 per annum for two years from October, 1961, will be according to qualifications and research experience.—Applications, with relevant information and two references, should be forwarded to Dr. W. A. Boggust, Department of Biochemistry, Trinity College, Dublin.

D.S.I.R.

Requires Scientific Officers/Senior Scientific Officers at the Water Pollution Research Laboratory, Elder Way, Stevenage, Herts, for the following posts: (i) Physical Chemists, preferably with good mathematical ability for research on physico chemical problems connected with treatment of industrial and domestic wastes and the effects of pollution on rivers and estuaries. Work includes laboratory studies and pilot plant investigations on unit processes, e.g., neutralization of acid or alkaline wastes and separation of solids from liquids in flocculating and non-flocculating suspensions (reference W.P.R.L.8 ZY). (ii) Physicist to work as a member of a team engaged in the development of indicating, recording and controlling instruments for use in the laboratory and field work in the study of rivers and the treatment of industrial and domestic wastes. The work is varied and covers a wide range of applications in physics, physical chemistry and nucleonics. The applicant should have a basic qualification in physics or physical chemistry, and an interest in electronics. Practical experience in instrument development or electronics, though desirable, is not essential (reference W.P.R.L.9 Y). Qualifications: First- or second-class honours degree in physics or chemistry. Salary ranges: Scientific Officer, £717 to £1,186. Senior Scientific Officer, with at least three years postgraduate experience, £1,302 to £1,604. Housing available in certain cases.

Application forms from Director at the above address quoting appropriate reference number. Closing date September 15, 1961.

DALHOUSIE UNIVERSITY

INSTITUTE OF OCEANOGRAPHY

Applications are invited for an academic post in experimental biology within which the appointee will conduct research on marine problems and undertake a limited amount of formal teaching. Appointments will be made at a rank and salary appropriate to qualifications. For a recent Ph.D. the beginning salary is $6,500.

Address all correspondence and recommendations to: The Director, Institute of Oceanography, Dalhousie University, Halifax, Nova Scotia, Canada.

UNIVERSITY OF ABERDEEN

Applications are invited for the post of Assistant in Animal Husbandry with special interest in Pig Husbandry. Salary on scale £800 to £950 with appropriate placing. Superannuation (F.S.S.U.), child allowance and removal allowance.

Further particulars from the Secretary, the University, Aberdeen, with whom applications (two copies), should be lodged not later than August 19, 1961.

PURPOSE IN PUBLICATION

UNTIL the middle of the seventeenth century practically all the major contributions to science had been made by men who possessed exceptional talents in other disciplines apart from scientific method. Aristotle, Bacon and da Vinci were not scientists in the way we think of them to-day: they were artists, moralists, and philosophers as well, and in those days of the non-specialist they had opportunities to pursue wide interests. To be a scientist to-day does not necessarily mean being a philosopher and artist too; but paradoxically, to be a 'good' scientist *alone* these days—a 'good' scientist being one who knows his 'literature' as well as his laboratory—is beyond the capabilities of many. This is not the fault of the scientist, nor is it due to any decline in intellectual grasp, but simply to the overwhelming mass of scientific literature which must be read to keep abreast of the subject.

It should not be deduced from this that, his scientific training and proclivities apart, the good scientist of to-day is ignorant about or, even worse, unaware of, other branches of man's culture. In fact, the contrary is true; indeed, so far as the community of scientists is concerned, the so-called 'two-cultures' (fashionably ascribed to C. P. Snow) scarcely exist. Many scientists are well read outside their own discipline, sometimes still within the ambit of science, but more often well beyond it—in philosophy, history, art, music, the theatre, literature, in fact, in the humanities generally. (Good scientists seldom make good politicians, which is probably understandable.) Some scientists of to-day have written authoritative treatises on music and musicians, and many are first-class musicians themselves; others have published poetry (in certain cases revealing that they are no mere poetasters); some have written highly successful novels; and, as used to be demonstrated at the annual meetings of the British Association for the Advancement of Science, a host of scientists are excellent pictorial artists and sculptors. T. R. Henn, lecturer in poetry and drama in the University of Cambridge, has said: "I am clear that all the great scientists that I myself have known have sought and invariably achieved some balance, some counterpoise, through a form of art, practised or enjoyed, which has taken a prominent place in their lives" (p. 537 of this issue).

In short, it is high time that the general opinion, still very extant, that the man of science is so wrapped up in his scientific literature and so confined to his laboratory that, apart from his calling, he is culturally unbalanced, be challenged. Indeed, the shoe is on the other foot; it is the student of, and savant among, the humanities, art, music and non-scientific literature (especially fiction) who are—and are often proud to admit they are—quite ignorant of science and its now 'jet-propelled' progress.

This unbalanced state of affairs in education and consequently attitudes must have contributed largely toward the movement which is fast culminating in science and technology being used for diplomatic intrigue, political propaganda, international threats and the consequent universal unrest.

It is relevant here to point out that the "Platform Party" at the opening of the magnificently posed Soviet Industrial Exhibition in Earls Court, London, on July 7 was comprised solely of Soviet and British statesmen (not including the Minister for Science) and a few others—but no scientists. Yet a very high percentage of the Exhibition was based on recent advances in science and technology. One can scarcely conceive of an exhibition of Soviet art in Britain or elsewhere being opened without the President of the Royal Academy (or his counterpart in another country) being 'officially' present.

This Exhibition clearly had a purpose other than trade. Yet, impressive though it was, it was not so revealing or informative as most trade exhibitions, and certainly not to be compared to its own advantage with, for example, the annual exhibition of the Physical Society. But advantage was obviously taken to publish a considerable amount of material, which was presumably read by many during, and after, the Exhibition. Many and varied handsomely produced brochures were made freely available. It should be borne in mind that these pamphlets will be read by some thousands of people, most of them not professional scientists, many not particularly interested in trade, and thousands of them very young and very impressionable. The background was mainly science and technology; so those responsible for the Exhibition left it to the Academy of Sciences of the U.S.S.R. to prepare some of the pamphlets. Excellently produced, some well illustrated and all issued between attractive covers, they are bound to command attention. Yet the text (in English) in each one gives a wrong impression of the *background* science which it sets out to describe. The result is that the layman will be left with the impression that nearly all the work (even back to the original) was carried out by Russians. It is true that the Exhibition was devised to show what is going on in the U.S.S.R.; but this is no excuse for confining the background, descriptive brochures to Russian work. For example, that on "Vegetative Hybridization in Plants" briefly mentions Darwin, Daniel and Burbank, then proceeds to devote the rest of its pages to Michurin and Lysenko. Of course, Vavilov is not mentioned. It is an old story, not improved by its re-telling, and significant in that it puts forward no new conceptions since the claims made by Lysenko about two decades ago. Geneticists will appreciate how misleading, therefore, this brochure is. That on "Physical Methods in Structural Analysis" states on p. 1 that: "Valuable results were achieved by G. V. Vulf, who, independently of W. L. Bragg, derived the formula underlying the X-ray diffraction analysis"; it then devotes nearly all the rest of its pages to present-day Soviet scientists. The brochure on "High Molecular Chemistry" adopts a similar approach.

In spite of the fact that these pamphlets were handed out at an Exhibition devoted to Soviet science and industry, it remains clear that they have been and are being read by many people, the majority of whom have scant scientific training. It can be safely assumed that few of these people will ask what contributions (original and more recent) have been made by scientists of other countries; so, to say the least of it, they will end their reading with a very distorted view of the world advancement of science.

In all these background brochures, produced under the auspices of such a distinguished scientific body as the Academy of Sciences of the U.S.S.R., very few (if any) scientists outside the U.S.S.R. are mentioned—and these only gratuitously. These leave anyone who has even an inkling of the subject in no doubt concerning the purpose of each brochure; and that is not to give a true picture of the history and present-day position of the subject. It is doubtful if many non-scientists will understand them, anyhow: they will just be overwhelmed with claims concerning Soviet achievements, and, thanks to their unbalanced education, perhaps, subconsciously, assume that nobody outside the U.S.S.R. has contributed or is contributing to the subject. The ill-informed make good material for insidious propaganda.

Coming now to the scientists in all countries, for they are not entirely blameless, they might well, with advantage to themselves and to world opinion, consider setting their own house in order. We hear much to-day about 'scientific jargon', 'scientese' and 'scientific Towers of Babel'; yet up to a point this is inescapable. The scientist must have his means of communication with his colleagues. The musician has his means of writing his scores (technically a 'language' which must be learned), and the artist also has his methods of presentation—quite often cryptic and sometimes even disturbing to the layman. It is understandable, therefore, that the non-scientist cannot comprehend much of the scientist's professional language unless the latter sets himself the difficult problem of interpreting his work in a more 'popular' fashion. (Writers of the Soviet brochures do not appear to have realized even this.)

But the 'language' of science has now got itself into such a state that sometimes even one scientist cannot understand another.

When, in 1665, the *Philosophical Transactions of the Royal Society of London* were first published, the stage was set for the scientific boom. There were 10 scientific journals in 1750, 1,000 in 1850, 10,000 in 1900, and to-day there are about 100,000. The number of journals has doubled itself every fifteen years or so since 1665 and would seem to indicate that by the year 2000 we shall have reached the million mark. Not only has the number of journals increased, but so also have the sizes of existing journals.

However, there are reasons for believing that the creation of new journals may not be as balanced a process as it might be. To take a specific example, the increase in importance of research in biochemistry, physiology and fundamental and applied biology has been very rapid during the past sixty years. (*The Biochemical Journal* was first published in 1906 and contained 495 pages; in 1926 the number of pages had risen to 1,376, and by 1960 to 2,510.) There is no reason for believing that the volume of publishable research work will decrease in the future, and one wonders whether, despite the startling rise in the number of scientific publications in general, there are enough journals to cope with the amount of material in pure and applied biology.

In the fields of mathematics, fundamental and applied chemistry and physics, and in technology, there are more journals and they are produced more frequently; as a result there usually is a shorter time-lapse between submission of the manuscript and its publication. This is not the case with the biological journals. There is none which deals exclusively with biological or biochemical research published more frequently than once a month ; indeed, most are produced quarterly or even less often than that. Consequently, papers accumulate in numbers which cannot be dealt with in current issues, and in a short time there is a long waiting list.

Nature itself now has a waiting list of biochemical, physiological and biological material in spite of the fact that the journal is becoming unbalanced because it is forced to contain so much on these subjects.

Nature is a weekly journal of science and as such produces items on most scientific topics. A glance at a recent issue shows, however, that in the "Letters to the Editors" section, about 70 per cent of the contributions are on topics of pure and applied biology. Of fifty-one letters, ten are in the biochemistry section and another ten under the heading of biology. It would seem that authors, not prepared to wait for their papers to appear in full elsewhere, will submit them to *Nature* first, with the intention of writing a detailed account for a more specialized journal later. The phrase, "Further details will be published elsewhere", is becoming a familiar sight to the Editors. The phrase is justified if the communication is confined to the gist of the research work; but frequently it turns out that the paper could not contain much more detail if the author(s) tried. Moreover, complaints have been received that the indefinite word "elsewhere" is tantalizing to those sufficiently interested and who wish to examine the details ; and, worse still, sometimes such "details" never see the light of day anyhow.

What is needed is either the creation of a new journal specializing in applied biology, biochemistry and physiology, to be published more frequently than the present ones, and/or for applied biologists and biochemists to use pre- and already- existing journals which have, for some reason or another, become 'unfashionable'. There is no doubt that there will be room for both these ideas as the amount of biological and biochemical research continues to increase.

The idea of a journal like *Nature* is to keep its readers informed about what is going on in *all* fields of science. Therefore, biological, physiological, and biochemical papers in particular, should be more brief and concise.

From another very serious point of view, the time-lag in publication of papers and even short communications is a blessing in disguise. It sometimes prevents authors from publishing erroneous results or unjustifiable conclusions. This, no doubt, is due not only to the enormous increase in scientific research throughout the world to-day but also to the tendency among far too many scientists to rush into print—a tendency all too prevalent and one to which the attention of the scientific world has been directed on several occasions in these columns. While waiting several weeks (sometimes even months) for publication after submission, research workers have found thrust on themselves time for reflexion, time for correction (sometimes necessary) and time for continuation of their work. It is no unusual thing nowadays for contributors to *Nature* to ask for their contributions to be withdrawn entirely or, in any event, returned to them because they have realized either errors in experimental method or in reading results or in coming to unjustifiable conclusions. Recently, on *one* day, letters for publication from three different groups of research workers were received asking for quite important changes to be made in their manuscripts already submitted, but (fortunately for them) not already published. Were it not for a certain amount of delay in publication, especially in the life sciences, the number of errata notes appearing in *Nature* would be deplorably high.

Another comparatively recent innovation, which is now becoming intense, is the establishment of so-called 'press relations' and the appointment of 'press officers'. This is, of course, not confined to science; in fact, scientific research centres are just following a general trend in this connexion. This will be all to the good for scientific advancement and information, provided it is carried out with tact, care and skill.

Nature has developed a close liaison with other journals, the newpaper Press and broadcasting organizations. Indeed, we consider this essential for both scientist and layman. Moreover, *Nature* has frequently advised scientists not to be too aloof and to do their utmost to assist the lay Press whenever their help can be of some specific value.

To-day, however, the tendency in this connexion among some scientific institutions and laboratories—academic, State and industrial—should be viewed with some concern. The number of so-called 'press hand-outs' and 'press releases' which reach *Nature* editorial office each and every day far exceeds the number of articles and communications submitted directly for publication. This might well undermine the general development and enhancement of science. For example, some press releases contain scientific results or claims that are quite fresh in that they have hitherto not been submitted to a learned journal or society for evaluation and possible criticism. Similarly, press conferences are so many and varied that they might well eventually defeat their own purpose. In any event, such 'exclusive' press releases often mean that some potential readers are missed, for it can be assumed that many such releases soon find their way into the editorial waste paper basket. The number received at *Nature* office each week would, if published, make a sizeable book. Press releases also result in duplication of publication. This may be all to the good where the lay Press is concerned (provided the material thus published in several newspapers is scientifically sound), for different people read different newspapers and magazines; but duplication in the scientific Press is highly undesirable, for undue prominence might ensue, and space is too valuable.

Nevertheless, in our own experience, press releases can sometimes be a nuisance (apart from the time-consuming job of reading them) and sometimes even dangerous. Too many of them exhibit the craze for priority or attempts to obtain the kind of publicity which is not always desirable. For example, recently a research publication was submitted to, and accepted for publication in, *Nature*. Shortly afterwards, a press release dealing with the same topic was received at *Nature* office before the original had been published. In order to keep as authoritative as possible, *Nature* very seldom publishes press releases in the form in which they are received; but on occasions they inspire the Editors to obtain an authoritative account of the subject. In the case cited, if the Editors had not noticed that the press release was a mere repetition (in different style) of what had already been submitted, double publication might have resulted in one and the same journal. The time seems ripe when editors of science journals must have a superhuman memory or possess some form of computer which will deal adequately with press releases.

Perhaps from the point of view of scientific advancement the most dangerous form of press release is that obviously written by a press officer who is not specifically acquainted with the subject under review but is doing his best to interpret some scientific finding to the lay Press. A further recent experience in *Nature* office will illustrate this. A fairly important discovery was made outside Britain by a scientist well known for his excellent work and publications. Yet a press release of his most recent discovery, presumably written by a press officer (this time in Britain), was received at *Nature* office. It was obviously meant for the lay Press, and some newspapers published it. Yet, when the Editors of *Nature* approached the scientist himself he disclaimed all knowledge of his discovery having been released to the Press.

Publication is one of the most important facets of the advancement of science. This applies not only to the scientific journal written by scientists for scientists but also to the lay journals and newspapers which are the forum for scientific exposition and discussion on the impact of science on society. In the past, far too many scientists have tended to remain aloof from the layman, and most have scorned any form of publicity. To-day, however, scientists are becoming increasingly aware of the effect of their calling on world society; this is no doubt due mainly to the tremendous strides science (and especially its applications) have made during the past few decades. Now, it is to be hoped that the pendulum is not swinging too far the other way. It is certain that claims for priority are uppermost in too many minds, and there is far too much inter- and intra-national competition and still not enough collaboration and team-work among laboratories and even nations.

Perhaps the most objectionable activity is that of the scientist who is determined that his light shall not be hidden under a bushel and therefore acts as his own press officer. Fortunately, in our experience such men are rare; but they are with us to-day, sometimes going so far as to notify the lay Press that they are about to publish in a scientific journal a communication in which the newspapers may be interested—even before they know whether the communication to the scientific journal has been accepted. Frequently succeeding in their endeavours, such scientific activities achieve publicity out of all proportion to their importance. There may be risks that ill-based claims are read and accepted by many readers.

Perhaps the day is not far off when scientists, through their means of publication, may be divided into the tough and the tender by a future William James, or the idealists and the realists by a future Schiller, or the "extraverts" and the introverts by a future Jung. It is certain that a future editor of *Nature* will be able to distinguish between the sincere scientist and the self-centred or personally ambitious scientist; but, alas, that editor may not live long enough to satisfy himself that the former is the more valuable member of any scientific team or community.

The scientist most desirable to science and society is he who leaves the evaluation of his work to his fellow scientists, presenting his findings with that modesty and dignity which one should always be able to associate with the word 'science'.

WHAT IS BASIC SCIENCE?

Disease and the Advancement of Basic Science
Edited by Dr. Henry K. Beecher. Pp. xi+416. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1960.) 100*s*. net.

THIS collection of articles illustrates the thesis that a study of disease can advance basic science. This thesis might seem self-evident, but it has not turned out to be so. During this century, and particularly in Great Britain, to try to understand Nature's experiments, as exemplified by disease, has tended to become scientifically disreputable. Thirty years ago Sir Thomas Lewis carried out a brief campaign for the recognition of clinical science as a discipline comparable in scope and status to those of other recognized branches of biology. He quoted the words of Sir James Paget of many years before: "I feel sure that Clinical Science has as good a claim to the name and rights and self subsistence of a science as any other department of biology; and that in it are the safest and best means of increasing the knowledge of diseases and their treatment. . . . Receiving thankfully all the help that physiology or chemistry or any other sciences more advanced than our own can give us, and pursuing all our studies with the precision and circumspection that we may best learn from them, let us still hold that, within our range of study, that alone is true which is proved clinically, and that which is clinically proved needs no other evidence". Lewis's advocacy produced an adverse response from medical scientists whose allegiance was primarily to the laboratory. In his presidential address to the Royal Society in 1934, Hopkins expressed the suspicion that the fields of clinical science so brilliantly exploited by Lewis and Mellanby were probably very few. He said: "I seem to have sensed, however, the beginnings of a definite movement in this country, and indeed elsewhere, not, of course, to ignore the laboratory; but in the distribution of funds provided for medical research to endow the Clinic on a scale which might endanger the future of research in fundamental biological science. The tenor of my remarks has been due to a conviction that in the long run such a policy would sterilize advance".

No detached observer would claim that the study of disease has made contributions to technique or to detail comparable with those achieved in the laboratory. But laboratory science has one major danger: it tends to be canalized into those lines that are, for the time being, most productive; the contemporary massive concentration of physiological effort into the behaviour of excitable tissues is an example. The unique contribution made by a study of disease is the prevention of too narrow an outlook and interest. How this has been and is being done is illustrated by the twelve articles in this book. Three may be quoted.

The first is unique, in that Linus Pauling conceived the idea that there might be molecular disease, that is to say, a disease the features of which were the direct outcome of the composition of a specific molecule. From what he was told of it, he wondered if sickle-celled anæmia could be due to a different form of hæmoglobin that crystallized out in the reduced form. This he was able to demonstrate. This story has recently culminated in Ingram's demonstration that normal and sickle-cell hæmoglobins differ by the presence of two amino-acid residues of valine in hæmoglobin S corresponding to amino-acid residues of glutamic acid in hæmoglobin A.

Bearn relates the story of biochemical genetics; how the story really began with Archibald Garrod, with his studies on the "Inborn Errors of Metabolism", albinism, alkaptonuria, cystinuria and porphyria. Garrod's work led him to consider that the abnormal gene resulted in specific biochemical abnormality which, in turn, gave rise to disordered metabolism and disease. This idea was revived, sharpened and more widely illuminated by the brilliant work of Beadle and Tatum on the eye colour of *Drosophila* and the nutritional requirements of *Neurospora* resulting in the one-gene/one-enzyme hypothesis. Bearn goes on to discuss the remarkable advances in our knowledge of copper metabolism produced by study of Wilson's disease, hepatolenticular degeneration, a disease transmitted by a Mendelian recessive gene and characterized by an inability to synthesize the copper-containing protein of serum, which, because of its colour, has been called ceruloplasmin. This is one of the more recent examples of how a genetically transmitted disease can illuminate biochemical mechanisms.

Perhaps the most enthralling story told in these pages is that of pernicious anæmia, first described by Addison in 1855. The break-through in this disease occurred when in 1926 Minot and Murphy showed that a diet of half a pound of liver a day would cure the disease, using as their index of response the percentage of immature cells, or reticulocytes, among the red cells of the blood. Minot and Murphy's trial of liver was based on a false analogy with experiments by Whipple, in which he had shown that liver was one of the most potent dietetic factors stimulating blood regeneration after bleeding in the dog. The analogy was false because the efficacy of liver in the dog was later shown to be due to its iron content, while in man post-hæmorrhagic anæmia has not been shown to respond to liver. There was an old series of observations suggesting that the primary defect in pernicious anæmia lay in the stomach, for Handfield Jones in 1854 had described atrophy of the glandular portion of the stomach in what was probably pernicious anæmia, and in 1870 Fenwick had shown that scrapings of the gastric mucosa, to which diluted hydrochloric acid had been added, failed to diminish the weight of a cube of egg white on incubation. The stomach defect had also been shown to precede the onset of anæmia. These two series of observations were brilliantly synthesized by Castle, who showed that if a normal subject was fed one pound of lean beef and made to vomit it at the end of an hour, and if the vomit was then fed to a patient with pernicious anæmia (as Castle remarked, *honi soit qui mal y pense*), the patient responded with a reticulocyte response and cure of the anæmia. Evidently, two factors were involved in the genesis of pernicious anæmia, an extrinsic factor present in lean beef, and an instrinsic factor present in the normal human stomach but absent from that in pernicious anæmia. The story is now nearly complete. The extrinsic factor is known to be the complex molecule of vitamin B_{12}, cyanocobalamin, the structure of which was so brilliantly identified by Todd and Hodgkin. The intrinsic factor still awaits precise definition, but there is no doubt that it is produced by the stomach and that its function is to facilitate the absorption of vitamin B_{12}.

These essays prompt the question: What is meant by basic or fundamental research? Listening to applicants for research grants, I would have very little doubt that the two adjectives have a substantial snob, prestige or prig value, as you care to look at it. All scientific workers wish to claim that what they do is basic or fundamental. The terms have also been applied to laboratory work as opposed to work outside it. Another usage equates basic science with pure science, the rest is applied. I have to confess that the intention to divide the pursuit of knowledge into fundamental and applied, into useless and useful, into respectable and unrespectable, has always been, and is, utterly repugnant to me. Knowledge is a unity, and an experiment devised and carried out in the laboratory is not necessarily more interesting or more illuminating than one designed, as it were, by the hand of God. It is at once conceded that it is often more difficult to apply the experimental method to the study of disease in man, and that to unravel the experiments of Nature is more difficult than to unravel those designed by man. But the present tendency to laud the laboratory and decry field work of whatever kind is not in the best interests of scientific knowledge as a whole. As Roger Bacon wrote, "All sciences are connected; they lend each other material aid as parts of one great whole. . . . As an eye torn out or a foot cut off, as it is with the different departments of knowledge; none can attain its proper result separately, since all are part of one and the same complete wisdom".

George Pickering

THE OCEAN FLOOR

The Floors of the Oceans

1: The North Atlantic. Text to Accompany the Physiographic Diagram of the North Atlantic. By Bruce C. Heezen, Marie Tharp, and Maurice Ewing. (Geological Society of America Special Paper 65.) Pp. xii + 122 + 30 plates. (New York: Geological Society of America, 1959.) 4.50 dollars. Physiographic Diagram 1.50 dollars.

Until very recently very little was known of the geology of the oceans, and rapid growth of interest and improvement of methods and instruments during the past fifteen years have led to striking advances. Improved echo-sounders, deep-sea corers, underwater cameras, towed magnetometers, shipborne gravimeters and other techniques have disclosed a new field for scientific exploration and geologists are rapidly taking advantage of it. Expanding interest in the history of the oceans, the nature and structure of the sediments and igneous rocks on the sea floor, and the processes at work, was one of the most striking features of the first International Oceanographic Congress held two years ago. The new idea of a borehole in the ocean floor was mentioned, and already an American team operating through water two miles deep has taken continuous samples from a borehole through 500 ft. of sediment and some 50 ft. of underlying rock.

The Lamont Geological Observatory, founded within Columbia University in 1949, has been outstanding in pioneering underwater geology, and this account of the floor of the North Atlantic Ocean by Heezen, Tharp and Ewing is based largely on first-hand experience. They show how they have been able to produce a "Physiographic Diagram of the North Atlantic Ocean" and outline its usefulness. The diagram is published separately for wall mounting, and it is the first of a series planned to cover the oceans of the world. It gives a striking portrayal of the general topography and roughness of the ocean floor. The horizontal scale is about 1 to 5 million, and the vertical scale has to be exaggerated by about 20 to 1 to bring out relief. It might be argued that this exaggeration over-emphasizes the slopes and the sharpness of features, but it is probably about the best compromise. There are nothing like enough soundings to base all the detail on fact, but the interpolation and extrapolation undoubtedly give as realistic a picture as we are likely to get for a long time.

The authors make some systematic classification by dividing the topographical features into three main types: continental margin, ocean-basin floor, and mid-ocean ridge, and subdividing these, sometimes tentatively, into component elements. The top part of the mid-ocean ridge, for example, is divided into rift valley, rift mountains, and high fractured plateau.

The distinctions they make are illustrated with the help of sounding records, bottom profiles, charts and underwater photographs, and, where possible, with the results of coring and dredging, magnetic and gravity anomalies, seismic soundings and heat-flow measurements.

Among the most remarkable features are the abyssal plains, where the underlying topography has been smoothed over by sediment-laden currents so that only the highest hills and seamounts stick out like islands from the surface of a lake. Mid-ocean canyons are steep-walled, flat-floored channels, 1–5 miles wide and perhaps 100 fathoms deep, cut in abyssal plains, generally in the approaches to steps to neighbouring, lower, plains. The mid-ocean ridge is about 1,200 miles wide with varied and irregular topography, and having a median rift, the rift valley, which, so far as we can see, is continuous down the length of the ridge.

Their new ideas are presented carefully, and, while giving much new information and many new ideas, the authors show where they need further support, and what we ought to do next. The book is a special paper of the Geological Society of America. Like several of the Society's publications, it will do much to further the study of the sea. It should be useful to cable companies, because of the new light it throws on some of the natural hazards and destructive processes that occur on the sea-floor. It has an excellent bibliography. G. E. R. Deacon

SECTOR-FOCUSED CYCLOTRONS

Sector-Focused Cyclotrons

Proceedings of an Informal Conference, Sea Island, Georgia, February 2–4, 1959. Edited by F. T. Howard. (Nuclear Science Series—Report No. 26. Publication No. 656.) Pp. xii + 291. (Washington, D.C.: National Academy of Sciences—National Research Council, 1959.) 2.50 dollars.

ACCELERATOR development has progressed with two main objectives in view: the first, to generate higher and higher energies, and the second, to obtain greater intensities. It was in the interests of this latter aim that the Sea Island Conference was held. Scientists from laboratories in America and Europe met to exchange information and ideas on the ways of increasing the intensities of medium- and high-energy cyclotrons by employing sector-focusing. It was fitting that L. H. Thomas, the first to expound this principle in 1938, should be among those present. Having been interested meanwhile in other subjects he could be forgiven his surprise at the delayed-action effect of his work.

The application of frequency modulation to cyclotrons in 1946 effectively solved the problem of obtaining higher energies but only at the expense of intensity, the continuous beam of the conventional cyclotron being sacrificed for a pulsed beam having a duty cycle unattractive for many nuclear experiments. For a time the attractions of the higher energies quenched the desire for greater intensity until of recent years its pursuit has been revived in several laboratories.

The *Proceedings* of the Conference record the papers and discussions at six sessions, the first of which was devoted to theoretical studies and orbit calculations. In this work, the use of large computers had proved invaluable. The achieving of the required magnetic field, however, was generally by way of successive approximations on an experiment model initially and later at full scale. Various methods of magnetic field measurement were described, many of which were mechanized to reduce the amount of repetitive work.

In the session devoted to radio-frequency problems novel approaches had been made in order to obtain a wide tuning range to give variable energy facilities. Then followed a session on quality of the beam, when interesting results were reported from several laboratories. This led naturally to problems of beam-extraction in which resonance phenomena, either deliberately induced or inherent in ridge-focusing, were discussed. The final session included a variety of topics relevant to experiments on cyclotrons, not the least important of which was that of shielding.

Approximately fifty papers were presented and the attendance of more than 80 is indicative of the wide interest in this field of work. Since the Conference several of the accelerators mentioned have come into operation. Perhaps these successes were in some measure helped forward by useful information exchanged there and certainly future workers will benefit from its recording in this series.

THE PROBLEM OF RETIREMENT

Growing Old in a Mechanized World

The Human Problem of a Technical Revolution. By F. Le Gros Clark. (Studies of Ageing within the Conditions of Modern Industry.) Pp. 147. (London: The Nuffield Foundation, 1960.) 7*s*. 6*d*. net.

MR. F. Le GROS CLARK, with the same clear insight into the urgent practical problems confronting the older worker, restates his theme and provides us with additional data. What is happening to and what is likely to happen to the working man between the ages of 60 and 75, if he remains in good general health, wishes to continue in employment, but because of declining powers finds it more and more difficult to hold his own in the conditions of modern industry ? What effect is the progressive trend towards mechanization and automation likely to have on the prospects of the ageing man ? To provide some data towards an answer to these questions, Mr. Le Gros Clark takes eight technologically advanced industries (motor-cars, rayon yarn, plate-glass, etc.) and examines the position of the older worker in sample factories.

His conclusions are fairly pessimistic—more pessimistic than those of his earlier reports, also published by the Nuffield Foundation. The accelerating progress of mechanization and automation is beginning to affect the prospects of the older employee. Not only is automatized work more demanding in itself (in the need for vigilance, paced performance, etc.) but also the range of alternative 'light' jobs to which older workers might have been transferred is becoming progressively limited. A rigidly imposed retiring age is making it increasingly difficult for the fit man of 65 or more to remain in employment. We must expect to find more and more men retired from manufacturing industry while they are still reasonably healthy. Are these men likely to find alternative work, if they wish to, in other fields of employment ? In a long appendix Mr. Le Gros Clark considers the older man's prospects in other sorts of work (road maintenance, gardening, public services, caretaking) and comes to the conclusion that most of these jobs cannot provide alternative employment for many manual workers who apply well beyond their middle lives.

So what can be done ? Mr. Le Gros Clark has two main suggestions : That we should call into existence new categories of light work (he mentions 'paid social work' but does not define what he means by this) : and that we should work out a new social theory of retirement. In other words Mr. Le Gros Clark is now (reluctantly ?) coming to the conclusion that the period of retirement is "the inescapable third period of life" even for those who are fit and well. "We have spent much of our time studying what chances we have of preserving the health of older men and of adapting factory conditions to their changing physique. We have spent even more of our time studying the needs of the infirm and aged. It is now our business to add to these a third and equally important field of research—that into the full meaning and content of retired leisure". This may well mean a re-casting of social values.

L. S. Hearnshaw

DALTON'S IRISH RIVAL

The Life and Work of William Higgins, Chemist (1763–1825)

Including reprints of "A Comparative View of the Phlogistic and Antiphlogistic Theories" and "Observations on the Atomic Theory and Electrical Phenomena" by William Higgins. By Prof. T. S. Wheeler and Prof. J. R. Partington. Pp. viii + 173 + xiv + 496. (London and New York: Pergamon Press, 1960.) 60*s.* net.

The mere sight of the title of this work will give historians of chemistry (and especially of atomism) great satisfaction. The biographical and critical matter which makes up the modern third of the volume could probably only have been produced by this collaboration of these particular authors. The publishers are to be congratulated on reprinting in facsimile the works of William Higgins, which are discussed in every history of atomism but can in fact have been seen by only few readers. It is an appropriate tribute to one of the many Irishmen who did so much to advance science in the eighteenth century.

The history of the early chemical atomic theory is not synonymous with the work of John Dalton, although he holds the centre of the stage. It seems to us now as if some re-statement of qualitative atomism in quantitative terms were inevitable at the close of the eighteenth century. However, this is historical wisdom after the event. We are not yet certain how Dalton's mind and those of his contemporaries worked. Did Higgins anticipate Dalton ? Did he influence Dalton ? Davy was prepared to say that Higgins's work had been important, but his authority has little value. False notions about the historical origins of their beliefs have often been held, and are often held now, by leading authorities in experimental science. The work which brings a man scientific eminence does not necessarily make him a reliable historian, even of his own field.

The controversies in which Higgins's name was prominent began soon after Dalton's theory was put forward, which was, however, long after Higgins's first book had been published and passed over. Higgins's *Comparative View of the Phlogistic and Antiphlogistic Theories* was printed in 1789 in London. It was a detailed refutation of Kirwan's *Essay on Phlogiston* of 1787 and is remarkable in being "the first English work to support Lavoisier".

At that time the phlogistonist controversy seemed overridingly important. Twenty years later, the newer system expressed in the theoretical language of Lavoisier was supreme. Higgins's advocacy was no longer relevant and the aspect of the book which became, and remains, interesting is Higgins's use of an atomic theory in expounding his antiphlogistic views. There is no doubt that he had a notable insight into the quantitative basis of chemistry, had grasped Lavoisier's teaching well and showed some originality in combining it with atomic ideas.

In some ways he was in advance of his time (as in his views on reaction mechanisms) and might have helped to advance chemical theory if he had possessed two qualities which in fact he lacked. One was the capacity to see wherein lay the fundamental novelty of a quantitative atomic system. The other was a capacity to express himself with clarity and self-evident consistency. Dalton possessed both these qualities, and although he may have failed to see all the consequences of his own theory, he certainly opened the eyes of his contemporaries quickly and effectively.

Dalton was recognized and honoured: in 1814 Higgins felt impelled to advance his own claims to priority by publishing his *Experiments and Observations on the Atomic Theory* reproduced in facsimile in this same volume. It could not give Higgins the high place he claimed, and which Wheeler and Partington conclude he could not justly claim. "Higgins has an honourable place in chemistry, but he does not stand on the same level as Dalton."

The notes, appendixes, and two sets of correlations between *Comparative View of the Phlogistic and Antiphlogistic Theories* and critical text are models of scholarly thoroughness. The biographical text is the first life of Higgins of any completeness.

This is not a biography for the beginner, who would in fact find much of it aridly dull. The authors have evidently not thought it necessary to extend their material by much connecting narrative or exposition intended to make its digestion easier. As an aid to study and as a record of ascertained fact, however, its faults are few.

It is not clear why the facsimile of the *Comparative View of the Phlogistic and Antiphlogistic Theories* is of the second edition, dated, so far as can be deciphered, 1791, when the earlier 1789 edition could have been used. So far as the text goes, however, this is unimportant, because comparison of facsimile with the first edition shows that the two are identical, errata and all. The errata have been corrected by hand in the original copy, but not in the original *Atomic Theory* copy. This is all of no real significance, but it is regrettable that, in my specimen at any rate, the *Comparative View of the Phlogistic and Antiphlogistic Theories* has lost the first page of the list of contents. The student will have to fill this small deficiency as best he may.

For the historian, yet to appear, who will write a worthy history of the early atomists, and will re-interpret them to a generation which consistently misrepresents them, this book will be an indispensable tool.

Frank Greenaway

SCIENCE AND POETRY*

By T. R. HENN, C.B.E.

President, St. Catharine's College, Cambridge, and University Lecturer in Poetry and Drama

I

THE attack on poetry, not by the scientist but rather by the man of common sense, is nothing new in history. Plato (who was, as Sir Philip Sidney pointed out, the most poetical of philosophers, teaching by means of the very myths and parables that his dialectic drove him to condemn) had banished the poets from his ideal "Republic". Some of his leading indictments are still current to-day; in our popular press, in the mouth of the common man, and in those jarring sects and faculties that compose a university. Poets are liars; *they say the thing which is not*. They encourage their listeners to give way to undesirable and womanish emotions, which should be repressed or governed by the intelligence. They tell lies about the gods. They give us examples of men and women doing what they should not; and thus cause others to commit, or at least to contemplate, the practice of evil things.

Now this general indictment is repeated, with differing variations, stresses and tones, from the beginnings of literature; most forcibly, perhaps, by the Tudor Puritans, who found, no doubt, some social justification in the contemporary ballads, and in the condition of the theatres as breeding places of both sin and plague. We may note the heavy cross-fire, from a slightly different angle, in Peacock's attack not only on his fellow-writers of the early nineteenth century but also on the general status and office of the poet. Whatever the function of poetry in the past ages may have been, he says, it was wholly out of place in his own "Iron Age of Industrialism". It is worth quoting a passage:

> "The descriptive poetry of the present age has been called by its cultivators a return to nature. Nothing is more impertinent than this pretension. Poetry cannot travel out of the regions of its birth, the uncultivated lands of semi-civilized man. Mr. Wordsworth, the great leader of the returners to nature, cannot describe a scene under his own eyes without putting into it the shadow of a Danish boy or the living ghost of Lucy Grey, or some similar fantastical parturition of the moods of his own mind. . . .
>
> "In the origin and perfection of poetry, all the associations of life were composed of poetical materials. With us it is decidedly the reverse. We know too that there are no Dryads in Hyde Park, nor Naiads in the Regent's Canal. But barbaric manners and supernatural interventions are necessary to poetry. Either in the scene, or in the time, or in both, it must be remote from our ordinary perceptions. While the historian and the philosopher are advancing in, and accelerating, the progress of knowledge, the poet is wallowing in the rubbish of departed ignorance, and raking up the ashes of dead savages to find gew-gews and rattles for the grown babies of the age. . . .
>
> "A poet in our times is a semi-barbarian in a civilized community. He lives in the days that are past. His ideas, thoughts, feelings, associations, are all with barbarous manners, obsolete customs, and exploded superstitions. The march of his intellect is like that of a crab, backward. The brighter the light diffused around him by the progress of reason, the thicker is the darkness of antiquated barbarism in which he buries himself like a mole, to throw up the barren hillocks of his Cimmerian labours. The philosophic mental tranquillity which looks round with an equal eye on all external things, collects a store of ideas, discriminates their relative value, assigns to all their proper place . . . is diametrically the reverse of that frame of mind which poetry inspires, or from which poetry can emanate".

II

I have quoted Peacock at some length because, with slight changes of emphasis and tone, it represents a considerable body of opinion to-day over the science-poetry controversy. We have swept away the myths, superstitions, "old furniture of the mind", the "Hebrew old clothes" on which are founded the "Magical View of Life" (the phrase is from I. A. Richards)[1] that once provided not only the materials but the very life-blood of poetry. It was a celebrated critic of a hundred years ago who advised Matthew Arnold to "leave the exhausted past". Science is the living example of reason in all things. It brings light, if not sweetness, to mankind. The history of science is that of the march of the intellect, a series of slow triumphs over ecclesiastical or political obscurantism, superstition and human stupidity. Science alone deals with *fact*, "susceptible, at every stage, of verification"; and exploiting, clearly and unequivocally, its practical 'goods'. It leads to the practical 'goods' of an ever-mounting standard of living, of medical care, of comfort, of speed, safety. It conduces steadily towards lighter and shorter hours of work. It gives man power over all things material. To such beliefs we are also inexorably driven, every day of our lives, by the assertions of commercial interests of every conceivable kind, whether overt or subliminal; and these assertions are not disinterested.

This is a common picture of a common belief: and at this stage of our discussion I wish to do no more than interject a quotation from Sir Charles Sherrington:

> "It was Joseph Priestley, writing . . . twenty years before the French Revolution, who foresaw issuing from Science a future 'glorious and paradisiacal beyond our imagination'. 'Nature . . . will be more at our command; men will make their situation in the world abundantly more easy and comfortable; they will probably prolong their existence in it, and will daily grow more happy'. The prediction was correct, save for its concluding sequitur, which as we hear it now rings as a non-sequitur. Priestley's enthusiasm had thought greater knowledge must mean supremacy of 'the values'. It might but it did not. In all this man can look for no help from any mind on his planet but his own. . . . He is the only recognizer of 'values' ".

III

Let us take the present disrepute of what Sidney called 'poor poetry' a little further. The artist or poet has, since the late eighteenth century, tended to appear to the public as a lonely, perhaps eccentric figure. Theseus's implied equation of him with lunatic and the lover dies hard in the mind of the common reader. He remains separate, in a real or imagined attempt to assert his own personality, his sense of his self-importance. He often sees himself as the one against the many. A suggestion of the *vates*, the prophet, the seër, has clung to him from the beginnings of history, and he is reluctant to jettison it. He has been in the past the inspired, even the afflicted (and therefore the venerated) of God. Many of Peacock's gibes still hold in popular estimation. If his audience believe neither in prophecy, nor in the world of the supranatural, nor in the existence of Spirit, his claim to attention may well be a thin one. As reverence for him diminishes, he is apt to clutch, even more tightly, the cloak of his real or assumed personality. The unpicturesque disorder of the 'beatnik' poet in Los Angeles or Greenwich Village is as much a badge of office as the long hair, the flowing tie, of the 'decadent', whether alcoholic or homosexual, of the 'nineties. There is more than a suspicion that his morality, particularly in sex, drink and drugs, will never stand the scrutiny of biographers, or even of the courts: the lives of the poets can be as unedifying to-day as they were, on occasion, to Johnson or Arnold.

---

* Substance of a lecture delivered at Hatfield Technical College on May 12.

With these things go a traditional inability or unwillingness to engage with any notable success in the world of action. We remember that Aeschylus recorded on his tombstone the fact that he had fought at Marathon, and left no word of his dramas. Sophocles commanded a squadron, and:

"Got laughed at, and went back to making plays,
Having allowed us our experiment
Respecting the fit use of faculty".

Chaucer seems to have been an efficient Civil servant and diplomat; Spenser did his job as what we should now call a military assistant to Lord Grey on his Irish Expedition. Marvell was a tolerable member of Parliament for Hull; Milton became First Secretary to the Commonwealth because he was the first Latinist in Europe. Byron had a military-political career that was both dramatically satisfying and reasonably efficient. But for the rest it is a depressing record of temporary and rather futile incursions into the active life—Gibbon, Coleridge, Wordsworth, Shelley, Landor are witnesses. In our time, in this century, I know of no major poet (with the possible exception of Wilfred Owen, who was killed at the crossing of the Sambre Canal on November 4, 1918, and of Sidney Keys in the Second World War) who was engaged in action; though I have known two generals who were minor poets themselves, and we may recall Roy Campbell, Brooks, Masefield and a few others. It is little wonder that our common man is suspicious of the poet's claims to supreme importance, to be the potential saviour of civilization, even to be the provider of a substitute for religion. It is very clear to the common man that poets are not, and never have been, Shelley's "unacknowledged legislators of the world". He can make no sense of Wordsworth's claim that "poetry is the breath and finer spirit of all knowledge". He observes with uneasiness that the poets, so far from facing up to their own particular problems, seem to be talking to their own small circle in a language of unexampled and ever-increasing complexity; and when, with a sense of relief and even pleasure, he turns to recognize his own sensible nostalgia in the work of Mr. Betjeman, he is told by the experts that this is not poetry. In the present literary scene the common man or scientist will note that only two literary figures of importance have taken degrees in science or mathematics, and he will reflect sadly that one has returned from defending poetry to a divided loyalty between the Coal Board and the B.B.C., and that the other is apt to write poetry which is comprehensible with difficulty even to the mathematicians themselves. (Curiously enough, there seems to be some tendency for biologists to be artists—perhaps because of much study of illustrative drawings—and for mathematicians and physicists to be musicians. Perhaps there is something of psychological interest here.)

IV

Let us start again. Very few poets have attempted any kind of 'liaison of vocabulary' between science and poetry. It is true that when science was younger it could and did lend to poetry material for metaphors; some elementary geometry for Marvell; optics, metallurgy, chemistry, a few medical terms, to John Donne; much alchemy, a little astronomy, and a vast quantity of astrology. It is, I think, true to say that no poet to-day would dare to take sides in verse in the Ryle–Hoyle controversy over the origin of the universe. "Never write a poem about the solar system" is a sound maxim; though I notice that this year at Cambridge the prescribed topic, "for a poem conducive to the honour of the Supreme Being and the recommendation of virtue", is "The Spacious Firmament". (But it is only fair to the University authorities to say that this was prescribed before the appearance of the space man.) There is a fair amount of contemporary science reflected in Shelley and Coleridge (in the main, chemistry and physics) and in Tennyson, who is strongly affected by Darwinism. The attempts to find, at the heart of the nucleus, an "Element of Purpose", suggesting the existence of creative mind, do not appear to me to have been very successful; nor is there (as Schroedinger has pointed out) any ascertainable relationship between the quantum theory and the problem of free will. It is true that certain possibilities of science in our time have stirred momentarily the poetic imagination. So D. H. Lawrence's *Relativity:*

"I like relativity and quantum theories
because I don't understand them
and they make me feel as if space shifted about
like a swan that can't settle,
refusing to sit still and be measured;
and as if the atom were an impulsive thing
always changing its mind."

or the attempt to find free-will restored by Einstein:

"But to one muddled mind it seems
A curvilinear universe
Involves free-will, and so redeems
God and the world from Calvin's curse."

But on the whole it seems as if modern poets distrust technological achievements; as in William Empson's poem "To an Old Lady" (which is the Moon):

"Project her no projectile, plan nor man it . . .
Landing, you break some palace and seem odd . . .
No, to your telescope, spy out the land :
Watch, while your ritual is still to see."

The poets seem, on the whole, to look backward with some longing to the period before the break-up of Hellenic and Hebrew mythological knowledge; consider Ronald Bottrall's *Eppur Si Muove:*

"there must be horse-sense, horse-strength, to spare
For building up into new stars
The molecules that the great machine
Has broken up into minute particulars
Remote from all that's viable and keen."

It will not work; any more than did Erasmus Darwin's *Botanic Garden*, or the *Loves of the Plants*. And although I have sometimes thought that some aspects of electronics might lend themselves to images in love-poetry—we might, for example, ponder on the possibilities of 'transistorized' and 'superheterodyne', or even of the experience of love as a 'reactor' rather than the classic 'crucible' or 'alembic' —it is clear that the 'multitudinous twittering polysyllables' of the average scientific paper do not lend themselves readily to rhythmic or musical utterance. Let us abandon all thought of these pseudo-marriages between the two sides, and start afresh with our argument. Poetry and science are separate, as human activities; and here I want to quote from Matthew Arnold:

> "It is the task of science to ascertain the facts of life ; and the task of poetry to relate them to human experience".

But what are the "facts of life" to-day; and how does poetry claim to relate them "to human experience" ?

V

Let me attempt to continue my case by postulating a scientist of high intelligence, who has studied (and on the whole assents to) the familiar case for the denigration of poetry, or at least the relegation of it—following Freud—to an auxiliary but peripheral activity. I should, I think, argue with him in some such terms as these.

In poetry we are concerned with statements of peculiar variety, strength and subtlety; and the operation of these statements we cannot pretend to understand without some agreement as to the nature and operation of the human mind; and in particular to the proposition that, whatever our claims to act under the stimulus of reason alone, the Emotional or E component, whether drawn from the conscious or subconscious, is of great importance. (There are, incidentally, grounds for believing that, for various reasons—which include those of the rapidity of modern communications—this E component is increasing rather than diminishing in the human situation.) Our thoughts and actions are conditioned and governed by a peculiar and varying blend of the R, or rational, and E components; and it is clear that, whether we "follow Priapus or Paul", Freud or Jung or Marx or Sartre, the single most important determinant factor is the past: whether in heredity, environment or upbringing. And this past is in itself a factor of incredible complexity. It is, inevitably, beyond and outside any accurate analysis or assessment by ourselves. It can only be reckoned with by a technique which makes use of a comparable delicacy and complexity in dealing with its effect. I am now hinting at a profound and difficult statement by Shelley, to which we shall return later:

> "Poetry administers to the *effect* by acting upon the cause."

Poetry is making statements about the nature of experience; experience that the poet perceives, organizes, refracts, and casts into moulds of the kind appropriate to his art. It is an art that is both more difficult and perhaps more satisfying than that of the painter, or sculptor, or musician; largely because the poet is using language as a multiple instrument. The formal technique of poetry must be recognized, studied, and, in a particular sense 'understood', if we are to receive what it has to communicate. The poet is making words perform peculiar yet precise functions; setting to work a complex selector-mechanism which can sometimes be shown analogically (as I have tried to do in a little book called *The Apple and the Spectroscope*) in mathematical and electrical terms; and if I were re-writing it, I should, I think, want to attempt to extend my illustrations into elementary chemistry as well. The selection, interaction and continuous modification of the meaning of words is made possible by setting them in complicated matrices of rhythm, tone, accent, pitch; themselves part of a relationship in terms of music which still further defines, amplifies and extends the meaning which the poet attempts to communicate. Further, he can and does use the method of perceiving correspondences between experiences (of events, people and objects) to indicate similarity and/or dissimilarity in that which he perceives, and hence can indicate judgments as regards value—whether positive or negative—regarding his perceptions. We may again refer to Shelley:

> "Reason is the enumeration of qualities already known ; imagination is the perception of the value of those qualities, both separately and as a whole. . . . Reason respects the differences, and imagination the similitudes between things."

But what is this poetic statement about? How can we explain its significance and what is the use of it, anyway ? What relevance has it to our problem of "Science and Poetry" to-day ?

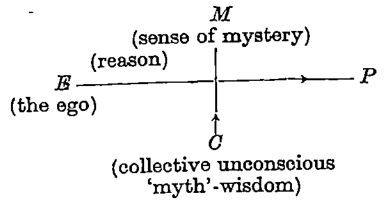
To some of these questions we can give brief but provisional answers. Poetry is 'about' the human situation, in its broadest terms. It is 'about' the highly complicated amalgam of intellect and emotion, of head and heart, of conscious and unconscious habits (but habits which grow and change continuously) that govern our normal lives. To the amalgam of the R and E components we are committed, inescapably, by the human situation. From the beginnings men have attempted to hack through the barrier, to behave in marriage, politics, war, as if humanity were (or might, one day, be) wholly 'rational' in its operations, as in the cold world of Swift's horses. It was in relation to love and marriage and woman's intuition that Meredith complained so bitterly:

> "Their sense is with their senses all mixed in ;
> Destroyed with subtleties these women are.
> More brain, O Lord, more brain, or we shall mar
> Utterly this fair garden we might win. . . ."

But it has not happened like that, and it will not: public and private history, religion, love, philosophy, all proclaim through time the irrationality of man. We must recognize that the greatest single danger to man's integrity and perhaps to our whole civilization is the subjugation of judgment by mass-media, before which even the perennial 'crooked questions' seem to be simplified for commercial or missionary ends; I mean those of love, death, pain, decay; of the essential dichotomy in the marriage relationship; of the existence of evil and tragedy; of the whole paradox of man's nature, the conflict between his 'erected wit' and his 'infected will', or St. Paul's great paradox (*Rom.* 7, 10). It is, I think, probable that we are to-day experiencing an induration or atrophy of the basic spiritual faculties; among those of sympathy, responsibility, and real (as opposed to fictitious or factitious) pleasure. And to this problem of sensitivity we must return.

VI

Now at this point I must attempt a brief excursion into metaphysics. Let us represent human experience by means of a tentative diagram, thus:



showing two poles or dimensions. The 'x' axis may be thought of as empirical in its nature; that is, it deals with the relationships and ideas that make up our normal common-sense world. Let *P* stand for the phenomena that compose our physical world. We may think of these as interrelated by laws of causality, themselves the proper objects of scientific inquiry. Let *E* be the ego which seeks to know the phenomena, which investigates and masters them. This horizontal axis of thought is Cartesian in origin. Along it moves pure reason which, rightly used, can solve all the riddles of the physical universe. Along this line the solution of the problem of the interrelations of all phenomena is possible. This solution is perceived as being in itself a 'good'.

Across this axis cuts the other[2]. Along it moves the 'community mind', *C*: which is not the 'mass mind' of war hysteria, or of popular riots. It is a mind which includes Jung's "collective unconscious", but is not limited to that concept, or to the analogous one of "The Great Memory" (as used, say, by W. B. Yeats). It grows slowly through the ages; it carries with it a store of collective wisdom in its myths. It moves on the vertical axis towards *M*, the sense of mystery in the world: and by mystery I mean those elements in the human situation which lend themselves only to intermittent apprehension, to which the approach cannot be made through rational or logical mechanisms; but which are of infinite importance in the total commitment of men.

I have very much in mind Jung's *Modern Man in Search of a Soul*; as well as the work of Joseph Wheelwright, Maud Bodkin, Austin Farrer and others. I believe passionately that the completed man needs the psychic satisfaction that is given by poetry, mythology, æsthetic experience: which, in many forms, can provide us with what Synge called "the nourishment, not very easy to define, on which our souls live". That this life of the imagination demands continually such nourishment, that it grows atrophied or indurated without it, I am certain. So long as there was a common ground of religious mythology (I prefer to use—following Jung and Kerényi—the word 'mythologem')—whether Biblical or Homeric—there was at least a common core of values, implicit or explicit, to be perceived in relation to them. The break-up of the common area of experience may perhaps be dated from about a hundred years ago, though something of it remained, I think, until 1914. We are familiar with *The Waste Land* of the 'twenties, the 'Pylon poets' of the 'thirties, the recurrent chorus that announced disintegration; and while the very act of perceiving that there is a disintegration is not without its value, we must clearly look for something more positive in character.

Now what this positive may be will depend, in the final analysis, on our own reading of the human situation. It seems to me improbable that poetry has much to give us if we accept wholly any of the empiricist philosophies, among them behaviourism that equates mind with the physical constitution of the body; instrumenticism which "reduces the meaning of any concept to that set of experimental operations by which the denotation of the concept can be objectively shown", and the fashionable semantic positivism which aims at a one-to-one correspondence between units of language and the sets or types of objects which such language units denote. Existentialism alone can point to a bitter ironical poetry of its own; since, while it jettisons many of the primary and traditional values, it holds fast to the status of the individual in his right of choice, in his need for integrity, nobility and courage; even though, to the existentialist, "life begins on the other side of despair".

Poetry does and must deal with the penumbral; and its penumbra may be the twilight world which reason and instinct, memory and present action, the conscious and the unconscious, merge imperceptively into each other. We read poetry because the inmost character of this penumbral world is only perceptible in the poetic statement, in the poem, in its own self-subsisting images, and not in any exegesis of it; because the fusion which it involves is its own highly complex justification; because its relationship to the totality of life is not perceptible without a study of its methods and techniques which can so easily atrophy, and which so often, in our present-day civilization, appears to give rise to a widespread aridity of consciousness.

It is at this point that I return to Shelley's

> "Poetry administers to the *effect* by acting upon the *cause*."

—that is, one operation of poetry is to produce, by exercising the creative imagination, the sense of awareness or sensibility which provides us with an extension of the individual towards unity with others and with the created world. Shelley in his time was arguing against the all-pervading rationalism, the *laissez-faire* economics of his time; and against that reason, unmitigated by pity, which had made "the rich become richer, and the poor become poorer". As he saw it, evil would in theory become impossible if all men were wholly sensitized and sensitive to the suffering of others; you do not do evil to others if your own imagination tortures you at the thought of their suffering. Perhaps this is what St. Paul meant by "charity", and some of us believe that various complex causes—among them the effects of two wars, the rise of the Welfare State, the rapid and violent re-orientation of communal values—have resulted in a diminished sense of pity and love, and perhaps of other virtues that are allied to these.

We can extend this thought a little towards the special problems of the scientist, whose work, habits of thought, pre-occupations with the *fact*, can and does distort or submerge, on occasion, his capacity for purely human relationships, whether in the family, in business, in the State or in international settings. I am clear that all the great scientists that I myself have known have sought and invariably achieved some balance, some counterpoise, through a form of art, practised or enjoyed, which has taken a prominent place in their lives: which seems to be the "nourishment, not very easy to define, on which our souls live". But one of them has suggested to me a further consideration: the possibility that some of the 'great' discoveries may now be going unmade precisely because so many students of science to-day allow their imaginative powers to atrophy. I have used the terms 'nourishment', 'feeding', 'exercise'; for I believe in its need for these things the imagination does not differ in kind from any other mental power. But unless it is exercised it does die quickly away; and with it that mysterious power of making the creative 'leaps in the dark', the habits of synthesizing, finding relationships between disparate events, ideas, and above all, perceiving values through comparison. How far this may be true, none of us, are, I think, competent to say. I can only judge from case-histories within my knowledge; in which the tremendous and ever-increasing pressures on the natural sciences student seem often to make it impossible for him to expand his interests in a manner which would ultimately permit him to bring a trained and flexible mind to the forming of value-judgments, and which, perhaps, diminish the probability that his creative imagination will contribute to his discoveries.

I do not, myself, wish to suggest that there is any difference in kind in the potential or the sensibility of, let us say, the mathematician as contrasted with the arts man in forming these value-judgments. What divergence there is seems to me to arise because of the manner in which the arts student is brought into continual contact with historical, political, philosophical and religious problems (however tangential or partial they may appear) that are refracted through the material which he studies. He thus becomes aware that such problems are highly complex, involving a number of indeterminate factors, and admitting of no quick or easy answer. Some experience of European diplomacy in time of war seemed to suggest the dangers of seeking for solutions that should in theory have been clear-cut, rapid, rational; when they were in fact the products of a slow maturation in time, and of immensely complex human and national factors that were themselves rooted in history. The search for the quick, the black-and-white answer seems to be an eternal temptation of the immature, the man or nation that is in too much of a hurry: and this (though I do not propose to enter into that discussion) is not without relevance to the problem of policy-making, and of taking central or seminal decisions, in industry and in international affairs.

VII

At this stage it will be seen that I am making no special claim for poetry as opposed to any other form of art that serves to feed this creative imagination; remarking only on poetry's greater complexity and 'impurity' of statement as compared with the statement of, say, music or sculpture. I myself believe that poetry has suffered from the zeal, and sometimes the arrogance, of its fanatical supporters. I had some early training as a mathematician, and I went to Cambridge as a modern linguist. I yield to no one in my love of poetry, and I carried much of it in my head during the Second World War, in many countries and in many crises both of personality, diplomacy and war. But I do not believe in the possibility that it should ever become a significant formative force over any considerable area of the national consciousness. It has always been, and I think it will remain, of limited though immensely important appeal and incidence. For poetry demands, like any other art, effort and study: whether it be Shakespeare, or Donne, or 'difficult' modern poetry. In theory all art should offer a delight that is easy, quick and having some considerable degree of universality. No art since the sixteenth century (perhaps the fourteenth) has fulfilled those conditions.

VIII

My own brief summary would, I think, run something like this:

Poetry can communicate to us, in a very special manner, the collective wisdom of generations of men and women. These experiences are (this is the price of their survival) archetypal and perennial; since they are rooted deeply in the human situation, in the conscious and unconscious, in the past and present.

By the peculiar (and still largely unexplored) methods of communication which embody a combination of the semantic and phonetic aspects of language, and by its devices of rhythm, which are strictly related to the total statement made, it can achieve an acceptance of vicarious or stated experience in such a way as to secure its integration into the human personality. It may and does become one 'experienced' aspect of the 'armour against fate'; and this over an unimaginably wide range.

By its presentation of integrated, shaped and organized experience (a play is a convenient example of this rhythmic structure) it satisfies our need for the intermittent perception of a complete experience in a world which, without art, we feel to be fundamentally chaotic, inchoate.

By its feeding, exercising of the imagination—which I would define as that faculty which enables us to be aware of the immaterial in its infinite forms—poetry can fill that perennial human need for a life in which the mythic element can obtain the psychic satisfaction which it requires. I do not hold, with Matthew Arnold, that "the greater part of our religion to-day is its unconscious poetry"; for I do not believe that poetry can ever be a substitute for philosophy or religion; even to those who may believe, as good agnostics, that they have swept and garnished the last room of their minds, and are merely waiting . . . for what ? I believe that poetry may prepare us for our journey into religion or philosophy, by just this process of sensitization, of increasing awareness, of which I spoke; I do not believe that it is a substitute. Nor do I believe (in contradiction to some of my colleagues) that a complete and implicit body of morality can or does arise out of poetry, since I believe that a body of moral belief, which must be won (at whatever cost) by the individual, is a prior necessity. I would argue that many of our problems to-day arise because of our attempts, in popular religions or in popular science, to short-circuit the long and painful processes of gaining knowledge and of adjusting that knowledge to the human situation. As for myself, I am certain that, if we are to allow the impact of any great art on us, we must be prepared to make certain assumptions (I am aware that many would give only a pragmatic assent, "the willing suspension of disbelief that constitutes poetic faith"), which I would set out as follows: (1) that there is a mind, or spirit, or soul, or psyche, which is not susceptible of explanation, as regards its powers and operations, on any known physio-chemical-biological hypothesis; (2) that the human situation involves the apprehension, intuitive in character, of a vast body of mystery,

Appearing in August

Advances in Aeronautical Sciences — Volumes 3 & 4

Editorial Committee Chairman : TH. VON KÁRMÁN

This 2 volume set contains the Proceedings of the 2nd International Congress in the Aeronautical Sciences, Zurich, including the 57 papers submitted and a full author and subject index.

Some Papers Published in Volume 3

The Role of Entropy in the Aero-space Sciences—DANIEL AND FLORENCE GUGGENHEIM MEMORIAL LECTURE—JAKOB ACKERET ; Possibilités et limites actuelles de la théorie des écoulements hypersoniques—J. P. GUIRAUD ; On the Use of Shock Tunnels for Research on Hypersonic Flow—D. W. HOLDER and D. L. SCHULTZ; and On the Theory of Hypersonic Flow over Blunt-nosed Slender Bodies—V. V. SYCHEV.

Some Papers Published in Volume 4

The Aerodynamics of Jet Flaps—JOHN WILLIAMS, S. F. J. BUTLER and M. N. WOOD ; Sub- and Super Alfvenic Flows Past Bodies—W. R. SEARS and E. L. RESLER ; and Einfluss des Start-Lende-Lastwechsels auf die Lebensdauer der Boenbeanspruchten Flugel von Verkehrsflugzeugen—ERNST GASSNER and KARL F. HORTSMANN.

Biological Waste Treatment

W. WESLEY ECKENFELDER, Jr., *and* **DONALD J. O'CONNOR,** *Manhattan College, New York*

Deals with the physical and biological principles of waste treatment and their engineering application to stream pollution analysis and waste treatment plant design. The book has a complete description of pertinent laboratory procedures and pilot plant design and operation. The most recent advances in research are applied to the design of treatment facilities, with emphasis on the mathematical quantitative approach.

All chemists, biologists, civil, design and construction engineers will find this comprehensive book extremely useful. It will be an essential reference work for all sewage boards, water boards and fisheries.

288 *pages* *illustrated* 65*s. net* ($10.00)

Progress in Microscopy

M. FRANÇON, *Professor of Physics, The Sorbonne, Paris University and Institute of Optics*

Describes the recent advances in methods used in microscopy. The first chapter is devoted to image formation, since this theory is essential in understanding the new techniques presented in the following chapters. The main subjects covered thereafter are geometrical measurements, interference microscopy, phase contrast, microscopy by reflection, observations inside the invisible spectrum (ultraviolet and infra-red), microspectrophotometry and microchemistry.

304 *pages* *numerous illustrations* 60*s. net* ($9.00)

Oogenesis — The Storage of Developmental Information

Chr. P. RAVEN, *Professor of Zoology, University of Utrecht*

This absorbing book gives an analysis of the formation of egg cells in the ovary, in which the synthetic and metabolic activities of these cells and their relationships with the surrounding elements are especially taken into consideration. These facts are discussed with reference to the problems of the transmission of information from one generation to the next through the germ cells. Conclusions are drawn on the possible mechanisms serving for the storage of this developmental information in the fertilized egg cell, and an attempt is made to derive reasonable estimates of the amounts of information involved.

Apart from its appearance, which we venture to think is considerably improved, there are no doors to open, the Nessleriser glasses can be more easily inserted and removed, and the design gives built-in provision for blue glass filters for use with white light attachments. Most metal parts have been eliminated. The range of interchangeable discs for use with the instrument provides permanent colour standards for some thirty analytical procedures, in addition to seventeen discs for pH determinations. The price, complete with any nine-standard disc and a pair of matched Nessleriser glasses, is £12.10s.0d.

which can be apprehended only by an intermittent and uncertain process of illumination, which grows, I think, less intermittent as we ourselves become older; (3) that poetry gives us one method of progress towards these apprehensions, and in particular of those that concern the penumbral—but not unfamiliar—worlds of which I have spoken; and which we exclude from our lives at our peril.

A quotation from Browning will serve:

> "Just when we are safest, there's a sunset-touch,
> A fancy from a flower-bell, someone's death,
> A chorus-ending from Euripides,—
> And that's enough for fifty hopes and fears
> As old and new at once as Nature's self,
> To rap and knock and enter in our soul,
> Take hands and dance there, a fantastic ring,
> Round the ancient idol, on his base again,—
> The grand Perhaps ! we look on helplessly—
> There the old misgivings, crooked questions are— . . ."

IX

No more than this, you say ? There is indeed; but my final judgment must be empirical, the result of watching many generations in their progress through literature and life. I am certain that the average undergraduate will one day be a better parent, lover, statesman, leader, for having read Shakespeare, Donne, Blake, Keats, Meredith. When he comes to his death he will die the better for having read, say, Dunbar, Donne, Herbert, Wordsworth. He will know better the essence of 'country'—and we neglect those roots at our peril—for having read Traherne, or Wordsworth, or Hopkins, or for having understood Constable's landscapes.

That is not to say that it would be better never to have been in love than never to have read Shakespeare. No literature of war can convey its full horror and exaltation and sense of futility until one has wasted years of life on it, or killed a man. Poetry, like all art, must demand and secure the perpetual opportunity to balance itself against physical life, experience; to test mutually the values thus discovered and embodied. Much of its disrepute is because of its claim to become an end in itself, the plaything of æstheticism, the spell-bound Lady of Shalott, the Sleeping Beauty in the jewelled sensual cave, or far worse than these, the esoteric speech of "the professors whose mouths are gorged with sawdust". Perhaps all that I am trying to say is summed up in an adaptation of a text that you will recognize. Its function is to give life, the strange and vitally energizing life of the psyche; and to give it more abundantly.

A STRATEGY FOR THE WAR ON HUNGER

By Sir JOSEPH HUTCHINSON, C.M.G., F.R.S.
University of Cambridge
and
Prof. A. H. BUNTING
University of Reading

THE Rockefeller Foundation instituted a public health programme in Mexico in 1919. By 1943, rising health standards there had produced one of the great modern human problems—the problem of feeding the rising population produced by scientific death control. In that year the Foundation and the Mexican Government inaugurated a co-operative programme in agricultural research which has served as a model for similar operations in other countries. Aided by this programme, an average annual population increase, during the past ten years, of about 3 per cent has been over-matched by an average annual increase of 7 per cent in food production. Seven per cent is one of the highest rates of increase of agricultural production recorded anywhere in the world in this period, but it is perhaps relevant to point out that while from 1948–52 to 1957 rice production in Asia increased at about 3·7 per cent per annum, in mainland China the figure was 5·7 per cent (calculated from *F.A.O. Mon. Bull. Statistics*, Dec. 1959).

Co-operation between the Foundation and the Mexican Government was based on a jointly supported and staffed operating unit, the Office of Special Studies, which was set up in 1943 within the Mexican Ministry of Agriculture. The Office of Special Studies has operated a number of research stations and has directed the scientific work in others. In the first instance the Foundation provided senior staff. From the beginning, they undertook the training of Mexican graduates, first on the stations in Mexico, and later in American universities. In this way fully trained Mexican staff became available to replace Americans in senior posts. In fact the development of the work has led to a continuing demand for senior American staff; but the proportion of the senior staff who are Mexican has steadily increased. In 1959–60, of a staff of 147, more than 130 were qualified Mexicans, and in 1960 it was possible to plan the unification of the Office of Special Studies with the Mexican national organization for agricultural research.

This general pattern of activity was repeated in Colombia from 1950, in Chile from 1955 and in India from 1956. Two international programmes have evolved from these experiences. The Inter-American Food Crop Improvement Program has been established to apply the collective experience of the Americas to food-crop research and production (specializing initially on wheat and maize), particularly in those areas of Latin America which do not have operating units of the Foundation. The International Rice Institute in the Philippines, which has also been aided by the Ford Foundation, is a joint enterprise of several rice-growing countries of south-east Asia.

The Rockefeller Foundation has now issued the first report of these activities*. Though nominally confined to a single year, it gives a clear account of the development of the programme and of its methods of work.

The programme is primarily agronomic in the broad American sense, covering the selection and breeding of food crops, forage plants, vegetables and stock, work on plant and animal pests and disease, on soils, and on weed control. If we add to this list agricultural economics and extension methods, we can discern the usual, and very effective, pattern of agricultural activity at State-level in the United States, where research is closely linked with the educational system and with the Federal agencies for more general or more fundamental studies. The programme clearly benefits greatly from the experience of the United States in handling the problems of areas of great geographical diversity, and from the great plant collections assembled by the United States Department of Agriculture. For example, the Inter-American Food Crop Improvement Program uses standard sets of wheat varieties, prepared by the U.S. Department of Agriculture, in different areas to determine the best-adapted types for different localities, in relation both to yield and rust resistance. A standard set of United States maize hybrids has been of great use, in the early stages of maize improvement work in various countries, in indicating the general varietal types most likely to succeed.

It is impossible here to summarize in detail the mass of useful work reported from so many regions; but a few of the points which seemed especially noteworthy may be quoted.

The largest single activity is the improvement of maize, followed closely by that of wheat and sorghum —three crops of which the United States has unique experience. Hybrid maize naturally occupies a central place. A hybrid maize programme has made remarkable progress in India, where double hybrids were to be released in 1960 for most of the maize-growing regions. In Mexico, a series of crosses between Mexican tropical varieties of maize and other Central American and U.S. material has initiated the modern exploitation of the vast genetic reservoir in the Latin American races of this crop. Work on the isolation of superior material by the testing of S_1 lines holds promise for the speedy improvement of indigenous maize. Remarkable progress, based on the American genetic collections, has been made in the improvement of sorghum and wheat. From the same country it is reported that "minute quantities" of potassium gibberellate (a spray of 1 p.p.m. at an unspecified rate) increased the seed yield of beans (*Phaseolus vulgaris*), while high-yielding bean hybrids will probably be released in 1962. A naked-seeded squash for oil extraction has been isolated. A blight-resistance breeding programme in potatoes has been based on *Solanum demissum*.

In Colombia, at Medellin, nearly 6,000 indigenous South American strains of maize, mostly from the Andes, are being preserved, partly in race composites (panmixis bulks), for breeding and research. Accounts of the races of maize in Chile, Venezuela and Ecuador will shortly be published, so that the indigenous maize of the greater part of South and Central America will then have been recorded by various hands. A new source of male sterility has been found in Colombian maize, and the development of broad-based synthetics for areas of less-advanced agriculture is foreshadowed. Important work on potato breeding using species other than *S. tuberosum* is also reported.

The most striking feature of the programme in India, where the Foundation has only six resident staff members, is the inauguration, in October 1958, of the postgraduate school at the Indian Agricultural Research Institute. In 1959–60 there were 186 M.Sc. and 113 Ph.D. students, following typically North American courses combining class-work and research training. The future intake is to be at the rate of 100 M.Sc. and 50 Ph.D. students a year. To write off this great educational effort as merely factory production of technologists would be to miss one of the most important features of such an enterprise in a country where there are many graduates but few trained and experienced research workers. The gap between a first degree and a fully trained research worker is extremely difficult to bridge in such circumstances, and the difficulties of the situation are enhanced by the problem of varying standards in the local universities. Such a postgraduate school is required not only to provide the advanced training that is necessary but also to give that degree of individual attention that is necessary if men of very different initial standards are to be turned out with a fair degree of comparability in experience and attainment. There is no doubt that the Indian Agricultural Research Institute postgraduate school will go far to meet a very real need.

The achievements of the Rockefeller programme must pose many questions for British readers. On a much smaller scale, the Empire Cotton Growing Corporation (also an unofficial organization co-operating with Governments) is in many ways comparable. Based on the genetic improvement of the cotton crop, its activities cover a wide agronomic range in several tropical territories, and in at least one it provides the backbone of agricultural research. Yet in territory after territory with which Britain has historical and still friendly links, it is proving extremely difficult to meet the demand for agricultural research workers and teachers. The Sudan Agricultural Research Division, once the finest organization of its type in tropical Africa, is at present seeking senior staff. For some years past western Nigeria has been attempting to recruit senior staff to build up agricultural research. At least two chairs of agriculture are vacant in English-medium tropical faculties, others have not been easy to fill, and several more are shortly to be created. How is it, that after sixty years of effective and successful agricultural research in all regions of the world, and a leading position in the related basic sciences, it is so hard to find British nationals for this work? Why, in India of all countries, was it necessary for an American organization to develop a postgraduate school in agronomy?

There are perhaps three groups of reasons. One is historic: the ending of the imperial regime usually means a feeling of insecurity for British employees, while the demand for improved educational facilities for the children of expatriates and for greater amenities for their wives often presents real difficulties.

The second and far more serious reason is that we are not producing enough of the right people. In England and Wales we have now virtually completed the deliberate and formal separation from each other of agricultural advice, education and research, the unity of which provides one of the great strengths of the American system. In no English university is there a field of real-life activity within which an agronomist in the broad sense can be trained. None of the university faculties of agriculture is large enough to provide the necessary range, especially since the advisory service, with its husbandry farms, has been separated from the universities. In some university departments, the trend of research interest, which inevitably comes to dominate teaching, is consequently forced away from the primary analysis and solution of practical problems towards narrow specialization and academic fundamentalism. In many agricultural research institutes it is very difficult for young research workers to qualify for higher degrees. Whatever one may think of the relative values of published papers and paper qualifications, it is undeniable that the discipline and criticism of a well-conducted higher degree course can play an important part in a research apprenticeship. Few British universities and research institutes have an active interest in tropical countries; neither the Agricultural Research Council nor any British university has a tropical field station for research on crops and soils; and no reciprocal arrangements for teaching or research exist between tropical centres and their British counterparts.

---

* The Rockefeller Foundation, 1961. *Program in the Agricultural Sciences*. Annual Report 1959–1960. Pp. ix+292+many plates and diagrams. (New York: Office of Publications, The Rockefeller Foundation, 1961.) n.p.

Thirdly, there are administrative reasons of which one or two may be mentioned. Secondment arrangements for tropical service and experience are rare, though secondment would often be possible without cost to home institutions, and secondment contracts of a suitable type could be a powerful aid to recruitment for overseas service. The formation of the Overseas Research Service does not yet appear to have increased the stability or sense of career security of overseas staffs, nor is the Overseas Research Council playing any effective part. The new Technical Assistance Department has an inspiring task and good leadership; if it can steer a way through the jagged reefs of its terms of reference it could have a great future—provided its course is outwards, to the deep blue waters of the stormy ocean, and not inwards to the sheltered calm of the lagoon.

This report of the Rockefeller Foundation under review can be recommended as wholesome and salutary reading for all who are concerned with the British effort in developing countries. United States participation in this field is increasing; and so powerful a reinforcement must be sincerely welcomed, particularly if it leads to a clear-sighted re-appraisal of the British position, and provides a stimulus to Britain's future efforts.

OBITUARIES

Sir K. S. Krishnan, F.R.S.

The sudden death on June 14 of Sir K. S. Krishnan, director of the National Physical Laboratory of India, at the age of sixty-two, is a grievous loss to Indian science in which he has been a leading figure for many years. Following his training at the American College, Madura, the Christian College, Madras, and the University College of Science, Calcutta, and a short period as demonstrator in chemistry at Madras, he joined the Indian Association for the Cultivation of Science, Calcutta, as a research associate in 1923. In association with C. V. Raman (later Sir C. V. Raman) he undertook a variety of researches in optics culminating in the discovery of the Raman effect in 1928, which was not only of immediate significance in itself, but also proved later to be an important tool for the study of molecular structure.

Shortly after, he became reader in physics in the University of Dacca and began a systematic study of the magnetic properties of dia- and para-magnetic crystals. This work continued and indeed bore its main fruit when he returned to the Indian Association as Mahendralal Sircar research professor in 1933. It is described in a series of papers, published in the *Philosophical Transactions of the Royal Society*, by Krishnan and his students during the 1930's. These are distinguished by the elegant simplicity of the experimental methods described (mostly devised by himself), and by the ingenuity of interpretation and the clarity of exposition. The results threw much new light on questions lying on the border between chemistry and physics, such as the arrangement of molecules in organic crystals, the structure of molecules, and the influence of crystalline fields on the paramagnetism of ions. During 1942–47 he was professor of physics in the University of Allahabad, and while still continuing experimental work on optics and magnetism began to interest himself more in theoretical problems such as the resistivity of solid and liquid metals. His election as Fellow of the Royal Society in 1940 and his knighthood in 1946 were very well-deserved recognitions of his scientific achievements.

In 1947 he was appointed director of the newly created National Physical Laboratory of India and with vigorous support from the late Sir S. S. Bhatnagar nursed it through its teething troubles to make it one of the largest and best-equipped scientific institutions of India. The award of the first Bhatnagar Medal to Krishnan shortly before his death was particularly appropriate and gave him much pleasure. During this time Krishnan gradually became one of the elder statesmen of Indian science: no official committee was complete without him, and he was much in demand for opening ceremonies and took an increasing part in international scientific affairs. He was, for example, vice-president of the International Council of Scientific Unions from 1955 and of the International Union of Pure and Applied Physics during 1951–57, and chairman of the Unesco Scientific Advisory Committee in 1955.

However, it must be admitted that though he felt keenly his responsibility as a public figure, administration was not really to his taste. In spite of all the calls on his time, he managed to keep going some active theoretical research of his own, to cultivate his mathematical talents and to read widely in many fields, by no means confined to science. I had the good fortune to spend a year at the National Physical Laboratory a few years ago, and the informal chats I had with Krishnan, particularly over lunch in the canteen, provide some of my most vivid recollections of that time. He never seemed to forget anything he had once read or heard, and had an encyclopædic knowledge in all sorts of unexpected fields. To illustrate an argument he was fond of quoting anecdotes about the great classical figures of physics, and this he could do in the most entertaining way. But he was equally at home in the latest developments of science and was a shrewd commentator on people and politics.

All this erudition was combined with great charm, good humour and kindness. His kindness, however, had its drawbacks when it came to administration, for he could not bring himself to say anything which would disappoint his hearer, and preferred to defer a difficult decision indefinitely rather than cause anyone disappointment. Another idiosyncrasy was that he could scarcely ever be persuaded to write a letter; thus a visit from him usually came as a surprise, preceded at the best by a telegram, but more often introduced by an apologetic chuckle as he explained that he had meant to write. His genial presence both at home and abroad will be sadly missed by a host of friends. He leaves a widow, two sons, four daughters and three grandchildren.

D. SHOENBERG

Dr. N. S. Shatsky

DR. NIKOLAI SERGEEVICH SHATSKY, member of the Academy of Sciences of the U.S.S.R. and director of the Institute of Geology, died in Moscow in November 1960. He was born there on August 28, 1895. He began his geological career as a stratigrapher, carrying out a detailed geological survey in the Donetz basin, and in the Caucasus and Volga regions. This work led him to the study of geological formations as stratigraphical units. At the same time, Shatsky was writing of oil and coal-bearing strata, iron ores, manganese ores and phosphorites. It was, however, in the field of tectonics that Shatsky excelled, and it is not without reason that he is considered to be the founder of a new tectonic school in the U.S.S.R.

His tectonic and palæogeological investigations in the European and Asiatic parts of the U.S.S.R. led him to establish a new Upper Proterozoic system, which he named the Rhiphæan system, and a new orogenetic epoch, coeval with this system, which he named the "Baikalian" epoch. However, his greatest achievement, shared with numerous collaborators, was a tectonic survey of the whole territory of the U.S.S.R., leading to the publication in 1956 of a most original, and in a sense most beautiful, tectonic map of the U.S.S.R. on the scale of 1 : 5,000,000. This map was the first of its kind. In it different colours were used for the major orogenic epochs and a number of tectonic structures were indicated by special signs. The Rhiphæan system and the tectonic map were briefly reviewed in Britain (*Proc. Geol. Soc., Lond.*, No. 1501, 108; 1953; and No. 1557, 29; 1958). Shatsky was also interested in the history of geology, and in 1941 he published, in Russian, a book on the life and work of the famous British geologist, R. I. Murchison, who greatly advanced the progress of geology in Russia. In March 1960, Shatsky was elected an Honorary Fellow of the Geological Society of London.

S. I. TOMKEIEFF

Mr. B. Welbourn

MR. B. WELBOURN, formerly director and chief engineer of British Insulated Cables, died on July 1 at the age of eighty-five. He retired in 1945 on the formation of British Insulated Callender's Cables, Ltd., through the amalgamation of the British Insulated Co. and Callender's Cable and Construction Co.

Mr. Welbourn graduated from King's College, London, in 1896. After a period of service with the Electrochemical Co. of St. Helens, he joined, in 1897, the British Insulated Wire Co., of Prescot, becoming contracts manager in 1902, in which capacity he travelled widely. In 1927 came his appointment as chief engineer, and in 1942 he was elected to the board of the British Insulated Co.

In a life-time spent in the electrical industry, in which he had such a notable career, Mr. Welbourn had served as a member of the Council of the Institution of Electrical Engineers, was a vice-president of the Institution and past chairman of the Manchester and Liverpool centres.

NEWS and VIEWS

Canadian Scientific Attaché in Washington: Dr. E. O. Hughes

DR. E. O. HUGHES, of the National Research Council of Canada, has been appointed as scientific attaché to the Canadian Embassy in Washington. While in Washington, Dr. Hughes will also serve as Canadian liaison officer at the British Commonwealth Scientific Office. Born in Wales, in 1916, Dr. Hughes received his initial education in Winnipeg, Manitoba, and Halifax, Nova Scotia. After undergraduate training in biology at McGill and Dalhousie Universities, he received an M.A. degree in 1939 from the University of Western Ontario. In 1942 he was granted a Ph.D. degree at the Ohio State University. During 1942–45 he was engaged in the administration of medical research for the National Research Council of Canada and the Royal Canadian Army Medical Corps. In 1945, Dr. Hughes became assistant professor of plant sciences in the University of Oklahoma, Norman, Oklahoma. In 1952 he returned to Canada as a research biologist and editor in the Division of Applied Biology of the National Research Council. His work was primarily concerned with the classification and physiology of freshwater algae. During 1956–60 he was assistant to the director of the Biology and Health Physics Division of Atomic Energy of Canada Limited, Chalk River, Ontario. For the past year he has been acting chief of the public relations office at the National Research Council of Canada.

C.S.I.R.O. National Standards Laboratory : Mr. N. A. Esserman

MR. NORMAN A. ESSERMAN, director of the National Standards Laboratory of the Commonwealth Scientific and Industrial Research Organization (Australia), has retired after twenty-three years service. Mr. Esserman graduated from the University of Sydney in 1916 with first-class honours in mathematics. He went to England in 1917 and worked in the Arsenal Branch of the

Munitions Office. On returning to Australia in 1920 he joined the Department of Defence, and afterwards became assistant superintendent of the Munitions Supply Laboratories (now the Defence Standards Laboratories) at Maribyrnong, Victoria. In 1938 he joined the Organization as officer-in-charge of the Metrology Section, one of the three units of the National Standards Laboratory. It was largely due to his experienced guidance that the Section was able to establish itself quickly and to make an outstanding contribution to Australia's war-time production. In 1958 he was appointed first director of the National Standards Laboratory. Mr. Esserman has been personally honoured by his election to the International Committee for Weights and Measures—a fitting climax to a career devoted to physical measurements and a tribute to the man who has had the unique distinction of playing the leading part in establishing the two main laboratories in Australia concerned with metrology.

C.S.I.R.O. Division of Mineral Chemistry : Mr. I. E. Newnham

Mr. Ivan E. Newnham has been appointed chief of the Division of Mineral Chemistry, Commonwealth Scientific and Industrial Research Organization (Australia). He is forty-one years old and graduated M.Sc. from the University of Melbourne in 1940. In 1942 he joined the Department of Aircraft Production and afterwards became supervisor of the Department's Testing Laboratories, where he was associated with the production of the first aircraft bearings made in Australia. During the later war years, while employed by the Newcastle firm of P. J. Taylor Pty., Ltd., he pioneered new techniques for the manufacture of automotive bearings. Since joining the Organization in 1947, Mr. Newnham's main interests have centred around the chemistry of the metals zirconium, hafnium and beryllium, all of which occur in Australian minerals. During 1950–55 he was engaged on research into methods for separating zirconium and hafnium, which occur together in the mineral zircon, in Australian beach sands. Pure zirconium is used as a container for uranium in the manufacture of atomic reactors, especially for use in nuclear submarines. Hafnium, which absorbs neutrons, is used for making control rods in reactors.

Physics at Sheffield: Prof. N. H. March

Dr. N. H. March has been appointed to the newly created second chair of physics in the University of Sheffield. He graduated at King's College, London, in 1948, and there began his research career under the direction of Prof. C. A. Coulson, then professor of theoretical physics at King's College. In 1950, March was appointed to an assistant lectureship in physics at the University of Sheffield, promoted successively to the grade of lecturer in 1953, and reader in theoretical physics only four years later. He has been an enthusiastic research worker from the beginning, and soon came to be regarded as one of the recognized authorities on the Thomas–Fermi statistical theory. In addition, he has maintained a lively interest in the electronic structure of molecules, in particular the electrical charge distribution. More recently, probably not uninfluenced by the activities of his experimental co-workers in Sheffield, he has turned to problems connected with the solid state. Here he has made important contributions to the distribution of charge around impurity centres. He now leads an active group of postgraduate research workers, and his school can confidently be expected to make substantial growth with the increased accommodation shortly to be available for the physics department in Sheffield.

Promotion of Science in Australian Schools

The fund which was established in England in November 1955, by a group of industrial organizations, to assist in increasing the number of scientists and technologists at the service of industry and of the country generally, has led to the establishment of a similar fund for a similar purpose in Australia. It was inaugurated at a meeting of industrial and commercial leaders, held in Sydney on March 20, 1958, under the chairmanship of Sir Edward Knox, and publicly announced on February 2, 1960. The Fund seeks to pursue its objects by stimulating and encouraging the teaching of science in suitable schools. Prior consideration is being given to independent boys' schools of standing, and the schools which are represented in the Headmasters' Conference of Australia are recognized as coming within this definition. It is intended to extend the range of consideration if sufficient funds become available. The Fund is now proceeding to assist chosen schools in the building of up-to-date laboratories and other rooms for the teaching of science. Attention is being given to the basic sciences, namely, physics and chemistry, and geology in suitable cases. Assistance to other sciences is not at present contemplated. In their discussion with schools, the Fund's representatives have endeavoured to encourage schools to plan with a long view so that it will be easy to add further accommodation later. The hope has been expressed that schools will endeavour to encourage a greater volume of science at the upper levels of secondary education and that they will seek to stimulate work of a more advanced standard. Contributions made or promised to the Fund to December 31, 1960, total £576,315. Although the amount is considerable, it is still far from sufficient to realize the Fund's full objectives, and more help is needed from others in the fields of industry and commerce. Further information about the Fund is described in a report which may be obtained from the Secretary, M.L.C. Building, Petrie Street, Canberra.

Shipbuilding Research in Britain

In the debate on shipping and shipbuilding in the House of Commons on July 13, the Minister of Transport, Mr. E. Marples, agreed that Parliament should attach the very greatest weight to research and development for both the shipping and shipbuilding industries. Better co-ordination is required in the future, he said, and shipbuilding research and shipping research should not be isolated departments but more and more together; this is now being discussed with the General Council of British Shipping. Referring to the loss of orders by the industry, to the charges of lack of modernization, inefficient management, demarcation and restrictive practices by the unions as well as to insufficient research and development, he said that a new and dynamic approach to production is required. The future of the industry is at stake, and for some time discussions have been proceeding between the two sides of industry about ways and means of improving its efficiency and removing obstacles to progress. If ths discussions do not achieve substantial progress in the near future, the Government intends to review the position with both sides of industry. Mr. Marples stressed the need for co-operation by both sides: without it we must fail. The question of research was particularly emphasized by Mr. A. Albu, and, in replying on the debate, the Parliamentary Secretary to the Ministry of Transport, Vice-Admiral J. H. Hallett, said that the British Shipbuilding Research Association is ably directed and undertakes research into production methods and techniques. It is hoped that the two industries will now jointly evolve some wider research organization which can handle problems of operation and of design and building as a whole, including possibly research on Diesel engines.

The Institution of Electrical Engineers

MUCH of the scientific work of the Institution of Electrical Engineers has been for many years conducted by four specialized sections (electronics and communications, measurement and control, supply and utilization). It has now been decided that it will be advantageous for the four sections to be replaced by three divisions, two of which will represent electronics and power interests, while the third, a general division, will cover activities of common interest to all electrical engineers, such as basic measurement, and technological education. Each of the divisions will comprise a number of technical groups designed to cover the specializations within its field, and the scheme provides for speedy re-adjustment and creation of those technical groups which will increase the flexibility which is now more than ever necessary to reflect the rapid developments of electrical science and engineering. In setting up a divisional structure, the Council has also recognized the increasing importance of electronics in electrical engineering, and the part being played by electronics engineers in the work of the Institution which has resulted in its present position as the professional home of electronics engineers.

Australian Journal of Experimental Agriculture and Animal Husbandry

THIS new journal is devoted to reports both on agronomy and animal husbandry. Judging from the contents of the first number, the journal is likely to cover a wide range of topics: it includes articles on the potassium content of some Western Australian soils, legumes in pastures, classification of Australian wheat varieties based on the granularity of their wholemeal and the relationships between digestibility of dry matter and digestibility energy content of ruminant diets. A pleasing feature is the inclusion of summaries of each paper in the list of contents—a departure which might be more widely followed. The journal is published quarterly by the Australian Institute of Agricultural Science for the Australian Agricultural Council and the subscription is £A.5 a year including postage.

Index Biologicus

UNDER the title *Index Biologicus* a periodical is being planned that will be a classified index of current papers from international literature in pure biology, giving titles, authors and journal references. It is intended that immediate notice will be given of all papers published in this already very extensive and rapidly expanding field, and that biologists will be provided with an information service comparable with those now available in other subjects, for example, *Index Medicus, Current Chemical Papers* and *Chemical Titles*. Scientific direction of the journal will be the responsibility of Biological and Medical Abstracts, Ltd., a non-profit company, limited by guarantee, that was formed by a number of learned societies when *British Abstracts* ceased publication so that the physiological and biochemical sections might be carried on. Like the present *International Abstracts of Biological Sciences*, which is the successor to Section *A* III of *British Abstracts*, the *Index Biologicus* will be published on a contractual basis for Biological and Medical Abstracts by the Pergamon Press. It is hoped that this publication will meet a real need and, moreover, it is expected that co-operation in the framing of scientific policy will be forthcoming from biological societies in Britain and overseas. The first issue of the journal is planned to appear in June 1962 or January 1963. Any comments or inquiries should be made to Dr. R. K. Callow, chairman, Biological and Medical Abstracts, Ltd., 4 Fitzroy Square, London, W.1.

Museum of English and Rural Life

THE annual report for 1960 of the Museum of English Rural Life at the University of Reading welcomes an acquisition from the British Council of some 300 examples of traditional design and fine workmanship (Pp. 19. 5 plates. Reading: The University. 1961. 1*s*.). The collection includes saddlery, wrought ironwork, small stools, turnery, basket work, pottery and textiles, and is of special value because the names and locations of the makers were known. More storage space has helped the re-arrangement of the reserve material, and increased workshop facilities have speeded the restoration of the larger farm implements and vehicles. The report of this organization is always noteworthy for the inclusion of notes on policy and other matters affecting the museum movement. On this occasion the curator, Mr. C. A. Jewell, contributes notes for collectors concerning the acquisition of folk-life material. It is rightly stated that traditional rural life in England was based on a relatively close-knit and self-sufficient community often with a distinct regional character. Although this has largely disappeared, scattered evidence still survives and practical and useful details are given on the collecting of objects and recording of information. The report is well illustrated.

Society for Folk-life Study

PLANS to form a Society for Folk-life Study will be discussed at a conference to be held in London during September 6–8, 1961. Membership will be open to all who are interested in the traditional patterns of life in both rural and urban communities, and especially in local dialects, crafts, folk-lore and customs. It is intended that the new Society will serve as a focus for the activities of all who take an interest in their cultural inheritance. Various well-known experts in this field of study have promised to speak at the conference. Further information can be obtained from Mr. J. G. Jenkins, St. Fagans, nr. Cardiff, who is the secretary of the steering committee.

The Nitrogen Problem

PROF. N. R. DHAR, in his presidential address to the forty-eighth Indian Science Congress held at Roorkee this year, reviewed the importance of nitrogen in crop production. He pointed out that synthetic nitrogen plants have been started in many industrially undeveloped countries, but they are handicapped by the heavy capital expenditure. The world demand for nitrogen fertilizers in 1960–61 is expected to be 8·1 million tons, of which Europe and the United States will together use 5·5 million tons. Prof. Dhar emphasized the desirability of building up phosphate reserves in the soil because natural fixation of atmospheric nitrogen in the soil is increased by adequate supplies of phosphate. Nitrogen is the key element in crop production; it is calculated that 100×10^6 tons of nitrogen are necessary for producing the world's food materials, excluding grass; but the chemical industry at present produces only 7×10^6 tons and legumes 5×10^6 tons. The nitrogen requirement of the world's grassland is estimated at 155×10^6 tons per annum, so that of the 250×10^6 tons of nitrogen necessary for the production of the major food crops of the world only 3 per cent comes from artificial fertilizers, 2 per cent from legumes, 2–3 per cent from precipitation and 2 per cent from organic manures. The rest is produced in the soil by microbiological activity on organic matter. Thus, industrial nitrogen supplies only a small part of the nitrogen requirement of crops, and a great deal can be done to increase land fertility by the better use of organic material supplemented by phosphate fertilizers to increase natural nitrogen fixation.

New Zealand Phytochemical Survey

During a survey of the New Zealand native flora for possible tumour inhibitory principles, extracts have been examined for the presence of alkaloids, leucoanthocyanins, saponins and triterpenes or steroids. In the latter work numerous fresh plants which are not extracted in bulk, and also herbarium specimens from the Auckland Institute and Museum, have been examined. The results of testing the New Zealand gymnosperms have now been reported (*N.Z. J. Sci.*, 4, No. 1; March 1961). The investigations show that alkaloids are not commonly found in species of the gymnosperms, notable exceptions being ephedrine from *Ephedra* species and taxine from *Taxus baccata*. No species of the New Zealand Cupressaceae or Podocarpaceae were found to contain alkaloids, but the heartwood of the sole representative of the Pinaceae, *Agathis austalis*, was found to give positive tests. The presence of an alkaloid has been afterwards confirmed when bulk samples of the heartwood were extracted and a water-insoluble alkaloidal fraction isolated in low yield. Attempts to isolate a pure compound have been unsuccessful. All the species gave positive tests for leucoanthocyanins, the barks of the plants being the richest source of these compounds. The isolation of the principle leucoanthocyanin from the bark of *Dacrydium cupressinum* has already been reported and has been shown to be a stereoisomer of leucocyanidin which is apparently not identical with any isomer previously isolated. That from the bark of *Dacrydium biforme* has also been isolated by one of the investigators but has not been obtained pure. It differs from that of *D. cupressinum*, giving delphinidin on hydrolysis.

Data on Research and Development

A preliminary report issued by the National Science Foundation (*Reviews of Data on Research and Development*, No. 28; June 1961. *NSF* 61–31) gives the capital expenditure of colleges and universities in the United States for research and development in the natural and social sciences in 1958 as 153·5 million dollars, of which 112 million dollars came from non-Federal sources. The remainder came from the Federal Government, being largely confined to the large research centres which colleges and universities administer for the Federal Government. Half this expenditure was in the biological sciences, 33 per cent in the physical sciences, 15 per cent in the engineering, and 3 per cent in the social sciences.

J.L.T. Industrial Research Fellowships

J. Langham Thompson, Ltd., are introducing a scheme of fellowships for young research workers, normally on a two-year tenure, with the intention that those appointed should carry out their research in the Company's laboratories in Watford, Hertfordshire. The fields of interest to the Company include: solid state, cybernetics, logical systems, electronics, circuit techniques, micro-waves, mechanics of solids, transducer techniques, optics. Candidates for these fellowships should have completed a higher degree, or have carried out original research of a high standard and have a clear appreciation of the research programme they wish to pursue. Further information can be obtained from J. Langham Thompson, Ltd., 176 High Road, Bushey Heath, Hertfordshire.

Sixth International Mineral Processing Congress

The sixth International Mineral Processing Congress will be held in Cannes during May 26–June 1, 1963. Organization is in the hands of la Société de l'Industrie Minérale and the following executive committee has been appointed: *President*, M. R. J. Testut; *General Secretary*, M. Pierre Gy; *Members*, MM. Astier, Emery, Ploix, Rey, Saint-Guilhem, Saverot, Seyer, Vielledent and Vuchot. As in the past, this Congress will be concerned with all aspects of mineral processing, and papers will be selected entirely on the basis of their scientific and technical value. However, the Committee wishes to place particular emphasis on the following subjects: (1) the concentration of iron minerals, including magnetic roasting but excluding agglomeration; (2) measurement, control and automation; (3) hydrometallurgy. Especial importance is also attached to the economic aspects of mineral processing and it is hoped that, whenever possible, authors will include data on installation and operating costs and comparative costs for alternative processes. The official languages of the Congress will be French, English, Russian and German, and provision will be made for simultaneous translation of discussions. An extensive series of visits to mineral processing plants and laboratories in Mediterranean countries will be arranged. The representative for the United Kingdom and the British Commonwealth is Prof. M. G. Fleming, Royal School of Mines, Prince Consort Road, London, S.W.7, to whom abstracts must be sent by October 15, 1961.

University News: Birmingham

Prof. William Henry Trethowan, professor of psychiatry in the University of Sydney, has been appointed to the chair of psychiatry; the date will be arranged.

Edinburgh

The following appointments have been announced: *Imperial Chemical Industries Research Fellows*, Juris Reinfelds (Adelaide) and Imre Laszlo (Debrecen), *Lectureships*, R. F. Thow (agriculture); Dr. L. M. Muggleton (electrical engineering); Benjamin Mitchell (veterinary surgery).

Leeds

New courses, leading to honours and ordinary B.Sc. degrees in food science, have been introduced, and the first students for them will enter the University in October 1962. The honours course extends over four years, and includes chemistry, physics, biology, statistics, bacteriology and biochemistry, taken in the appropriate pure science department in the first year. This is followed by courses in the chemistry, physics and microbiology of foodstuffs and food processing. The ordinary degree course is restricted to three years. Entry requirements include a high standard in chemistry and physics, with mathematics as the preferred third subject. The Procter Department of Food and Leather Science, under the Procter professor, A. G. Ward, has grown from the former Department of Leather Industries and will receive extended premises and additional staff for the new course. Postgraduate students will be able to take the postgraduate diploma in food science, involving study and research, or carry out research for the M.Sc. and Ph.D. degrees.

London

Mr. S. B. Watkins, head of the Department of Chemical Engineering at King's College, has been appointed to the University readership in chemical engineering tenable at that College. The title of reader in pure mathematics has been conferred on Dr. K. W. Gruenberg in respect of his post at Queen Mary College.

The title of professor emeritus has been conferred on the following: Prof. R. O. Buchanan, professor of geography in the London School of Economics and Political Science since 1949; Prof. L. P. Garrod, professor of bacteriology in St. Bartholomew's Hospital Medical College since 1937; Sir Austin Bradford Hill, professor of medical statistics at the London School of Hygiene and Tropical Medicine since 1945, and honorary director of the Medical Research Council's Statistical Research Unit; Sir Christopher Ingold, professor of chemistry in University College since 1930; Prof. W. H. Linnell, professor of pharmaceutical chemistry in the School of Pharmacy since 1944, and dean of the School; Prof. C. A. Mace, professor of psychology in Birkbeck College since 1944; Prof. D. M. Newitt, Courtauld professor of chemical engineering in the Imperial College of Science and Technology since 1945; Prof. F. R. Winton, professor of pharmacology in University College since 1938.

Announcements

The Earl of Halsbury, during 1949–59 managing director of the National Research Development Corporation, has been elected president of the Machine Tool Industry Research Association.

Dr. F. A. Robinson, at present director of research of Allen and Hanburys, Ltd., has been appointed chairman of the board of directors of the Crookes Laboratories in succession to Mr. N. B. Smiley, of Arthur Guinness, Son and Co., which acquired the Crookes Laboratories jointly with Philips Electrical Industries last November. Dr. Robinson is honorary treasurer of the Biochemical Society and the author of books on chromatography, antibiotics and the vitamin B complex.

Colonel J. F. Williams-Wynne has been appointed a member of the National Parks Commission. Colonel Williams-Wynne is a part-time member of the Merseyside and North Wales Electricity Board and a member of the Regional Advisory Committee of the North Wales Conservancy of the Forestry Commission and the Gwynedd River Board.

Lord Shawcross has been appointed a member of the Medical Research Council. He will serve as chairman of the Council in succession to Viscount Amory, who is resigning on his appointment as United Kingdom High Commissioner in Canada.

Mr. A. W. Jones (Fleming Radio (Developments), Ltd.) has been installed as president of the Scientific Instrument Manufacturers' Association of Great Britain for the year 1961–62 by Mr. G. C. Ottway (W. Ottway and Co., Ltd.), the retiring president, who now becomes a vice-president. The following honorary officers have been elected: *Vice-President and President-elect*, Mr. R. E. Burnett (Marconi Instruments, Ltd.); *Vice-President*, Mr. G. C. Ottway (W. Ottway and Co., Ltd.); *Secretary*, Major W. Logan (Avo, Ltd.); *Treasurer*, Mr. G. S. Sturrock (Kelvin and Hughes, Ltd.).

To celebrate the third centenary of the birth of Antonio Vallisneri, a past-president of the "Accademia Patavina di Scienze Lettere ed Arti", the University of Padua is organizing, during September 29–October 1, a symposium on "The experimental method in biology from the time of Antonio Vallisneri to the present". Further details can be obtained from the Organizing Committee, University, Via 8 Febbraio, Padova.

The Electronics Group of the Institute of Physics and the Physical Society announces that it is arranging a conference on "The Physics of Gas Discharge Devices", to be held at Leamington Spa during September 28–29. Further information can be obtained from the Administration Assistant, Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

New Laboratories for the Division of Food Preservation, Commonwealth Scientific and Industrial Research Organization, will be opened at North Ryde, New South Wales, on September 18. A Food Science Conference will follow, during September 19–22. Further information can be obtained from the Chief, Division of Food Preservation, Commonwealth Scientific and Industrial Research Organization, P.O. Box 43, Ryde, N.S.W.

The Autumn Meeting of the Institute of Metals will be held in Brussels during September 18–22. The programme includes the Autumn Lecture, to be delivered by Baron Snoy et d'Oppuers on September 18 (who will speak on "The Non-Ferrous Metals Industry in a Unified Europe"), and sessions on deformation and fracture, on surface friction and lubrication in metal working and on corrosion. Further information can be obtained from the Institute of Metals, 17 Belgrave Square, London, S.W.1.

Erratum. In the issue of July 29, p. 439, the date of birth of Sir Frederick Gowland Hopkins was given as June 30, 1861; this should read June 20, 1861.

LONG ASHTON RESEARCH STATION, BRISTOL

THE staff of the University of Bristol Agricultural and Horticultural Station at Long Ashton includes 47 graduate scientific officers and now totals 225, approximately double the pre-war figure. The basic work of the Station on all aspects of fruit culture and fruit utilization has similarly expanded, and there has been, in addition, a rapid growth in biochemical studies related to plant nutrition, a development stimulated by the formation in 1952 of the Agricultural Research Council Unit of Plant Nutrition (Micronutrients), the members of which were assimilated into the Long Ashton staff in 1959.

These increases in staff and research programmes have necessitated new laboratories and ancillary services. A comprehensive building scheme for the Station was drawn up in 1949, and, although the proposed plans have not all been implemented, a substantial instalment of the programme has now been completed. On July 6, Sir William Slater, formerly secretary of the Agricultural Research Council, declared open the buildings that have been constructed during the past five years. Of these, the three principal are : (1) a range of experimental glasshouses with attached laboratories and special-purpose rooms; (2) a refectory/common room adaptable for use as a hall for lectures and meetings; (3) the Wallace Laboratory, named after Prof. T. Wallace who retired from the directorship in 1957 after having served the Station for thirty-eight years.

The Glasshouse/Laboratory block, a building of 43,000 sq. ft., has six separate glasshouses, each 72 × 34 ft. with a ridge-height of 24 ft., constructed of a suspended 'Aluminex' framework with side walls infilled with 2-ft. brickwork. The houses, from west to east, are used respectively for propagation, plant nutrition (two houses), pomology, plant pathology and entomology. Each glasshouse communicates by a short corridor to a header house 220 × 18 ft. The southern half of the header house, adjacent to the glasshouses, forms an open gallery; the northern half is divided to form laboratories, stores, cold rooms and special-purpose rooms with controlled environment. A set of rooms for work on radioactive tracers is segregated at the east end of the header house; the west end houses the services for soil and plant preparation.

The main boiler house, attached at the west of the glasshouse block, contains three oil-fired automatic-

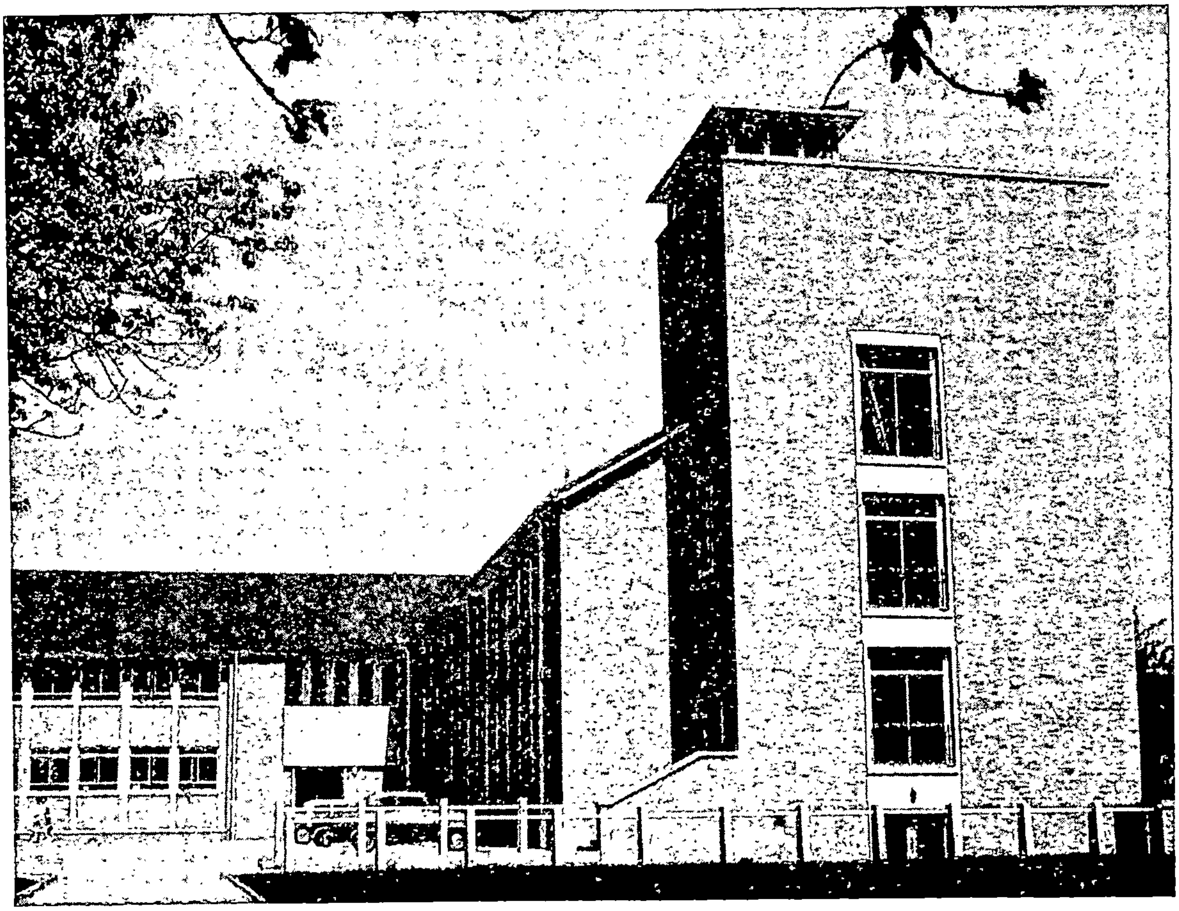

Fig. 1. The Wallace Laboratory of Long Ashton Research Station

ally controlled McNiel boilers, providing space heating and hot water for the glasshouses, the refectory and the Wallace Laboratory. Steam conveyed through underground conduits supplies heat exchangers for the production of hot water, which is passed through radiators, ceiling coils or hot-air circulators.

The Refectory/Common Room is a single-storyed building covering 5,300 sq. ft. It is faced with 'Reformite' reconstructed stone and has large french windows overlooking a pleasant expanse of the fruit plantations. The roof is of double-Roman tiles and the floor of polished Iroko wood blocks. The dining hall, 60 × 37 ft., connects through a folding partition to the common room 35 × 37 ft. With the partition open a hall 95 × 37 × 20 ft. high is provided. There is a well-appointed kitchen equipped with air extractors and refrigerated larder. The building is heated by a hot-air circulatory system linked to the main boiler house.

The Wallace Laboratory is a two-storyed, T-shaped building of 24,000 sq. ft. floor space, roofed and the walls faced in the same style as the refectory (Fig. 1). The entrance hall is panelled in apple-wood veneer cut from a tree of the cider variety 'Knotted Kernel' which formerly stood on the site. Some of its sister trees of the original cider orchard (planted in 1904) still flourish around the new laboratory. The western arm of the building houses the administration section on the ground-floor, and laboratories for analytical chemistry above. The southern limb of the ground-floor accommodates the pomology and plantations sections, with stores and organic chemistry on the first floor. The remainder of the ground-floor has laboratories for physical chemistry, statistics and willow research, with the section for nutrition of fruit plants above. There are extensive basement rooms for stores and heat-exchange equipment, with a tower at the southern end housing the water cisterns and capped by an observation platform for meteorological recording. The lofts house elaborate fume extractors and 'Plenum' heating equipment.

Among other buildings is one of 8,400 sq. ft. consisting of laboratories for biochemistry and plant physiology which was completed in 1956. During 1959–60, the director's room, the committee room and the library in the Barker Laboratory (the original laboratory building) were redecorated and re-furnished. Extensive improvements and additions have also been made to workshops, machinery sheds and roadways.

R. W. MARSH

THE BRITISH IRON AND STEEL RESEARCH ASSOCIATION

THE Sheffield Station of the British Iron and Steel Research Association, where open days were held on June 15 and 16, houses three of the Association's five main research divisions—the Steelmaking, Metallurgy (General), and Mechanical Working Divisions.

Steelmaking

The Steelmaking Division is responsible for research into all the modern processes involved in the conversion of iron into steel, and prominent among its present research projects are the control of electric-arc and open-hearth furnaces, continuous casting, and the use of oxygen in steelmaking operations.

The use of large electric-arc furnaces for the bulk production of steel is increasing and it is expected that, in 1965, these furnaces will account for one million tons more of Britain's total annual steel output than in 1960. Economy in the use of electrical power is becoming, therefore, a matter of increasing importance. The automatic power input controller (*Apic*), which has been developed recently by the Steelmaking Division for application to electric-arc furnaces, has already shown itself capable of achieving significant reductions in electricity consumption. Trials have been carried out satisfactorily on the Association's experimental furnace at Sheffield and on a 5-ton production furnace at Steel, Peech and Tozer, and further trials are now being carried out on another member's 30-ton furnace.

Continuous casting helps to achieve higher yields and greater uniformity of end product. A number of continuous casting plants has recently been installed or projected, including a twin-strand plant at the Abbey Works of the Steel Co. of Wales. This is based on the process developed by the Association in conjunction with the Continuous Casting Co. of Weybridge, and will be used for casting low-carbon slabs up to 48 in. × 8 in. in section. The Steelmaking Division's present investigations into this new process are directed mainly towards improved moulds and mould reciprocating cycles. Arising out of these investigations, a new design of mould has been evolved which enables three interconnected ingots to be cast simultaneously, these being afterwards separated and treated as individual castings.

During the past few years there has been a dramatic increase in the use of oxygen for steelmaking processes and the new vessels now being introduced into Britain, such as the *L.D.*, *Kaldo* and *Rotor*, will alone probably account for something like 14 per cent of the total annual steel production in 1965. In addition to pure refining duties, however, oxygen can be used for flame enrichment in open-hearth furnaces and also for pretreating hot metal. The Division is at present conducting trials of a new hot-metal pre-treating device which employs a simple reversal of the converter process principle. With this technique—termed spray refining—instead of passing oxidizing gases through molten metal, the metal is teemed through jets of oxidizing gas, thus breaking up the falling stream of metal and—by increasing the effective metal surface area—promoting rapid and efficient refining reactions.

The current research programme of the Steelmaking Division also includes investigations into control of open-hearth furnace combustion, the rapid desulphurization of electric steel and studies of subcutaneous segregates.

Metallurgy

The Metallurgy (General) Division is concerned with the physical, chemical and mechanical properties of iron and steel, and the effect on these properties of variables in the manufacturing processes. The Division's activities are divided into the broad categories of physical properties, mechanical properties, metal treatment and metallurgical analysis.

Research into physical properties is at present focused on the magnetic characteristics of silicon iron. During 1960, electrical power to the value of eleven and a half million pounds was wasted as a result of losses in silicon iron transformer cores. A reduction of as little as 5 per cent in these losses would result in an annual saving of more than half a million pounds. The Division's investigations into the factors contributing to core losses have already shown that reductions of up to 15 per cent could be obtained.

A better understanding of the factors affecting the fatigue limit of steel would greatly improve the possibilities of achieving better dynamic mechanical properties in high-tensile steels. Also in the context of mechanical strength, it has been established that the presence of certain elements in mild steels affects their resistance to brittle fracture at low temperatures. The Division's work in connexion with the mechanical properties of steel is mainly concentrated on these problems, although research is also being conducted on the mechanism of fatigue and more economical methods of fatigue testing.

Metal treatment research, the third of the Metallurgy Division's spheres of activity, consists primarily of investigations into methods of degassing molten steel. The presence of certain gases in steel often has a significant effect on the qualities that are expected of it. Excess hydrogen, as a specific example, may lead to cracking and other undesirable flaws in the finished product. The Division is at present engaged in investigating two methods of hydrogen removal by degasification techniques. In the first of these a continuous vacuum degassing unit is used, molten metal being poured into an evacuated chamber, degassed at a pressure of about 1/1,000th atm. and discharged into air. In the second method—termed 'jet degassing'—the hydrogen is removed by blowing a neutral gas such as argon, nitrogen or helium on to the surface of the molten metal by means of a lance. This second technique has achieved a reduction of eight parts per million to one part per million in the hydrogen content of an eight-pound melt, and the possibility of using this method on a larger scale is being examined.

The increased throughput rates which have been made possible by the use of oxygen in steelmaking practice have thrown greater emphasis on the need for faster metallurgical analysis. In addition to developing faster and more accurate physico-chemical analytical procedures, the Division is also therefore investigating the application to steel works requirements of the newer physical techniques of direct reading and X-ray fluorescent spectroscopy and electron-probe micro-analysis.

Supplementary to its main research programme, the Metallurgy (General) Division also provides services to other research divisions and departments of the Association, to industry, to research organizations and to universities.

Mechanical Working

The Association's research into all the processes by which ingots are formed into wrought metal products is carried out by the Mechanical Working Division. This Division's research programme is therefore spread over a wide range of manufacturing processes which may be broadly classified by end-product—sheet and strip, forgings, rounds and sections, and wire.

Because of the superior quality of product obtainable, the use of continuous annealing for blackplate has been increasing in the tinplate industry during the past few years. However, conventional continuous annealing plants are very large and costly, and inflexible in operation. Investigations by the Division on an experimental annealing line at the Swansea laboratories have resulted in the development of a process which, by greatly reducing the pass length, makes possible the use of a more compact plant, with a considerable saving in costs. Products of a commercial quality have been obtained and plans are now in hand for the installation of a pilot production plant at a member's works.

Other features of the Division's research into sheet and strip manufacture include a new process for aluminizing steel strip, the electrolytic smoothing of blackplate, investigations into the prevention of scale formation on coiled strip, and three new in-line inspection techniques. Some fundamental work is also being conducted by the Association's Physics Department on tandem-mill automatic gauge control with the aid of a new analogue computer which has been installed recently at the Battersea laboratories of the Association.

In the manufacture of forgings the Division's main research project is the automatic programme control of forging presses and manipulators. Simple programmed forging operations have already been carried out, both more rapidly and more accurately than in manual operation, and more complicated schedules are now being formulated. Forging research has also resulted in the development of a new procedure for closing ingot cavities by upsetting, and a heat reflector arrangement which, by conserving the heat in the workpiece, has proved capable of achieving a 30 per cent reduction in heating requirements. In addition, the Plant Engineering and Energy Division is at present conducting investigations of batch type forge furnaces on behalf of the Mechanical Working Division.

The Division is also now working on a number of problems associated with wire manufacture—such as wire cooling, continuous wire inspection and control, and the welding of high-carbon steel wire—and the manufacture of rounds and sections.

Development and Information Services

The Sheffield Station also houses the Steel User Section of the Association's Development and Information Services. This Section employs the Association's research resources to assist individual companies in their use of the industry's products. The services which it provides range from answering simple technical inquiries to more complicated investigations into metallurgical and other production problems.

The remaining research divisions and departments of the British Iron and Steel Research Association are located, as in the case of the Sheffield Group, in the area of the country most appropriate to the work for which they are responsible. The Ironmaking Division, for example, has a pilot-plant laboratory at Normanby, near Middlesbrough on the north-east coast, and a blast-furnace laboratory at the Imperial

College of Science and Technology in South Kensington. The Plant Engineering and Energy Division is based at the Association's Battersea Research Station, as are the Physics, Chemistry and Operational Research Departments, and there is also a laboratory at Swansea, in the South Wales tinplate area, where some of the Mechanical Working Division's research into sheet and strip manufacture is conducted. The Association's headquarters are at 11 Park Lane, London, W.1.

THE INTERNATIONAL COUNCIL FOR BIRD PRESERVATION

THE seventh Conference of the European Continental Section of the International Council for Bird Preservation was held in Stavanger, Norway, during June 19–24, and was attended by representatives of the National Sections of Austria, Belgium, Denmark, France, Germany, the Netherlands, Norway, Sweden, Switzerland and the United Kingdom, together with representatives of the International Wildfowl Research Bureau, Conseil International de la Chasse, International Union of Biological Sciences, and the International Union for the Conservation of Nature and Natural Resources.

The destruction of sea birds by waste oil has become a permanent item on the agenda of all conferences of the International Council, and it was noted with great satisfaction that Poland had ratified the International Convention for the Pollution of the Sea by Oil, and that the U.S. Senate had voted 92–0 to ratify this convention. The adhesion of Poland to the convention is of particular importance to Scandinavian countries for it now only requires the support of the U.S.S.R. to enable steps to be taken to declare the whole of the Baltic a prohibited zone for discharge of oil. The area in the Baltic in which oil discharge is now permitted has resulted in heavy pollution, particularly on the coasts of Sweden, where it has caused such great destruction of the long-tailed duck (*Clangula hyemalis*) that it is feared the status of this species is endangered. The representatives of the Netherlands, where systematic counts of birds killed by waste oil are carried out throughout the year, reported that there were distinctly less than before, and this statement was also supported from Belgium.

A resolution was adopted welcoming the decision of the Inter-Governmental Maritime Consultative Organization to convene, in the spring of 1962, a further conference on oil pollution of the sea, and urging that priority be given to the complete avoidance, at the earliest possible date, of discharge of persistent oils into the sea, and to the immediate provision of adequate facilities for the disposal of oily wastes at refineries, ports of loading and ports of discharge. The resolution further urged National Sections to press their Governments to instruct their delegates to the Inter-Governmental Maritime Consultative Organization conference in 1962 to support action on these lines.

The prejudice against any bird with a hooked beak dies hard, and though some countries reported an increase in certain species it was generally agreed that birds of prey were still being destroyed on a large scale and many species had critically decreased. The need for education on the valuable part these birds play in the balance of Nature was expressed in a resolution which also recommended that if an examination is required to secure a shooting licence a knowledge of identification of birds of prey should be required, in order that protected species should be distinguished from those allowed to be shot.

The destruction of bird life as a result of the use of pesticides has reached such proportions as to cause grave concern all over Europe, and a resolution was passed requesting Governments to adopt legislation by which all pesticides must be officially tested not only with regard to their effect on noxious animals and plants but also on wild life in general before they are permitted to be sold. Further, that Governments be urged to encourage research on the use of specific pesticides and other methods which limit the destruction of wild life, and to forbid or place drastic restrictions on the use of general pesticides that are dangerous to wild life, wherever effective and less dangerous materials can be made available.

The great increase in herring gulls (*Larus argentatus*) and the harm these cause to other species, particularly in Germany and the Netherlands, has been a problem for many years. In the Netherlands methods of control have been carried out with great success, the number of breeding pairs in 1959 and 1960 being reduced to almost half that of 1954. One of the factors in the great increase of this species is the easy availability of food in winter, through fish offal at ports, rubbish dumps, etc. In Denmark there is no problem as all fish offal is collected and used for food in mink farms or for fertilizers.

The present policy of land drainage in certain European countries, whether it be economic or not, presents a serious threat to many species of water and wading birds, and two areas in particular were the subjects of special resolutions. The first, the Marismas of the Guadalquivir in Spain, is the richest area in western Europe for marshland birds, particularly as regards migrating and wintering species. The disappearance of these marshes would mean not only the loss of the main European breeding ground of several rare species but would also have irreparable consequences to the status of migratory marsh birds in many European countries. On June 1 an international delegation of representatives of the International Wildfowl Research Bureau, the International Council for Bird Preservation, and the International Union for the Conservation of Nature and Natural Resources, with the Consejo Superior de Investigaciones Cientificas of Spain was received by the Minister of Education in Madrid to consider the possibility of acquiring an area of the Marismas as a reserve and to establish a biological research station there.

The second area, the Baie de L'Aiguillon (Vendée) on the Atlantic coast of France, with its large expanse of mud flats, provides an exceptionally favourable resting place for migratory birds which breed in northern Europe and rest there on their spring and autumn migration. The project to drain this area, for agricultural purposes of doubtful value, in a country where there is no lack of agricultural land is being strongly opposed by both French naturalists and sportsmen and their colleagues in other countries.

The proposals concerning the establishment of Council of Europe machinery for matters concerning nature conservancy and national parks were considered, and the prospect of a closer relationship between the Council of Europe and organizations for conservation of Nature was welcomed.

Among other subjects discussed were the traffic in European birds for cageing, bird protection in schools, the danger of the airgun and the increase of the starling (*Sturnus vulgaris*).

Prof. Sven Hörstadius (Sweden) was unanimously elected chairman of the European Continental Section in succession to Dr. Bøje Benzon (Denmark), and Dr. Gerth von Rokitansky (Austria), vice-chairman, in succession to Dr. G. A. Brouwer (Netherlands). Prof. S. O. Hörstadius, a former president of the International Union of Biological Sciences, was accorded an honorary degree by the University of Cambridge during the tercentenary celebrations of the Royal Society in 1960, and it may be apt to quote the Orator's citation on this occasion:

"We read in Lucretius these lines about the origin of animals: 'And many monsters also did the earth then try to create, springing up with strange face and limbs'. She did so to no purpose. But this man does the same to very good purpose. For beginning his studies from the egg in no mere proverbial sense, and using incredible penetration of mind and dexterity of hands alike, he has taken to pieces, down to their smallest components, the embryos of sea-urchins, worms and amphibia, and then re-assembled these into new animal organisms. Would anyone have believed before that two tissues cut from an embryonic newt combined could co-operate to form cartilage, and that, with the addition of a third, tooth would result ? What wonderful metamorphoses, and advantageous indeed to men ! For from this he has thrown light on the influence of part upon part and organ upon organ in the gradual construction of the adult animal, which could be of great value to the art of medicine. So we salute one who has at last set foot on the true way in an inquiry raised by Aristotle himself.

"But do not imagine he only examines and handles eggs. For he is an observer of the ways of birds, and in that most pleasant branch of study also has won world-wide fame.

"I present to you a professor of Uppsala, worthy heir of the studies of Linnæus of Uppsala—Sven Otto Hörstadius".

PHYLLIS BARCLAY-SMITH

IMMUNITY TO PROTOZOA

In the age of Metchnikow and Ehrlich, the subject of immunity had not become divided into the separate compartments of bacteria, fungi, protozoa, etc., as it has to-day, and a broader view was possible at that time. A recent symposium, organized by the British Society for Immunology at the Middlesex Hospital during June 1–2, represented an attempt by the Society to reverse the trend and to bring workers of one specialized field (protozoology) into the classical milieu. Various aspects of immunity to protozoa were thus presented, and, to some extent the idea of the Society was successful, many interesting papers were given, and these provoked some discussion.

The subject of the symposium, "Immunity to Protozoa", was introduced by P. C. C. Garnham, who gave a short historical survey, then a summary of the histological basis of immunity and finally a review of acquired and innate immunity in the parasitic protozoa. In his opinion, the realm of innate or natural immunity offered at present the most promising opportunities for research. All degrees of resistance of the host to the organism are found, which may be influenced by various internal factors like unsuitable blood components (later ably described by A. C. Allison in regard to the inhibitory action of sickle-cell hæmoglobin and glucose-6-dehydrogenase deficiency on *Plasmodium falciparum*), by external factors like removal of the spleen, and lastly by the site occupied by the parasite in relation to its host: immunity thus may be unable to touch the parasite when it is safely enclosed within a parenchyma cell of the liver, yet immunity will kill rapidly when it lies in an exposed position in the blood stream.

The symposium was honoured by the presence of Edmond Sergent, who came from Algiers to give a lucid account of premunition, a subject which has occupied him for the past 60 years and which he here crystallized into 26 precise definitions. Premunition is the basis of the subject, and yet has been much misunderstood; it was useful to have it described by the *Maître* himself. On the other hand, premunition is not the only form of immunity, and A. Corradetti described examples of true residual immunity in rats which had recovered from *Plasmodium berghei* and *Trypanosoma lewisi* infections respectively; in some cases, nothing could break down this resistance, and he clearly showed that the protozoa had been completely eliminated by the immunity response, while the rats proved to be immune for life.

Much of the original work on the cellular basis of immunity was carried out by W. H. Taliaferro, by his wife Lucy, and his collaborator, H. Mulligan. All these workers were present at the symposium, and the subject was introduced by W. H. Taliaferro, who described briefly the lymphoid-macrophage system and then went on to more recent work of a biochemical nature. This indicated that under the influence of the growth-inhibitory antibody, 'ablastin', nucleic acid synthesis in *T. lewisi* comes to a stop, although protein synthesis may continue at a low level. He also considered the phenomenon of 'avidity' or antigen-binding capacity. His explanation of the development of immunity in *T. lewisi* infections by the successive appearance of several different types of antibody was challenged by W. E. Ormerod, who suggested that the disappearance of young and dividing forms (the earliest of which inhabit the protected environment of the kidney capillaries) was not due to 'ablastin' but to an ordinary type of antibody which had a selective action on the young forms.

The subject of immunity cannot properly be considered apart from the nature of the damage inflicted by the parasite on the host, in other words, the mechanism of pathogenicity. B. G. Maegraith illustrated this by reference to non-invasive strains of parasites, which later change their habits and attack the tissue so that an increasing degree of virulence is attained. In *Entamoeba histolytica*, the special enzyme production of an amoeba determined its pathogenic potential. The actual cause of injury was thought, in the case of malaria, to be a soluble toxin which acted on the mitochondria of cells, destroyed their membranes, and brought respiration to an end. The chemical composition of this agent is still not precisely known, but it appears to be non-specific. This work seems to be on the brink of important new discoveries.

The symposium then continued by examining the phenomenon of immunity in: (*a*) blood infections; (*b*) tissue infections; (*c*) infections of the skin and mucous membranes, including the intestinal tract. The last-mentioned group stood out from the rest because some localization of immunity was often apparent.

Immunity in malaria was discussed by Avivah Zuckerman. *In vitro*, macrophages exposed to malarious chicken blood, in the presence of hyperimmune homologous serum, phagocytosed numerous normal as well as parasitized erythrocytes. Furthermore, in a series of simian, rodent and avian malarias, more anæmia occurred than could be attributed to destruction of red cells by emerging parasites. An autoantibody was postulated to explain these observations, and Coombs' tests were positive in two rodent malarias during the period of excessive anæmia. However, since positive antiglobulin tests were also observed in other anæmic states from which parasites were absent, the autoantibody hypothesis remains moot.

L. J. Bruce-Chwatt gave an interesting account of the variability of immunity in malaria inherited by an infant from its mother, and which might be derived either via the placenta (particularly in human beings) or via the milk (in rodents). There was no doubt of its existence in the hyperendemic regions of tropical Africa, and it formed a valuable barrier to infection in the earliest days of life, though the effect quickly wears off. Transplacental immunity is probably the explanation of the unexpectedly low rates of occurrence of parasites in infancy. The exact mechanism is still unknown, and it was suggested that the subject might be investigated further in monkeys, where the placental structure was not unlike that of the human.

Immunity in piroplasmosis was considered by R. Riek, and in a written communication by S. F. Barnett. The former described babesiosis in Australian cattle, demonstrating once more the peculiar tolerance of calves to *Babesia* infections in contrast to the susceptibility of the adults. He made some interesting references to the pathogenic effect of this organism, when present in a high density, on the invertebrate host, a subject which had been little discussed, perhaps because the arthropod is normally immune to any harmful effects of the protozoon which it carries. S. F. Barnett divided the *Theileria* species in cattle into three immunological groups: (1) *T. mutans* ; (2) *T. annulata*; (3) *T. parva* (which includes *lawrencei* and *bovis* in addition to *parva*). The last-mentioned group behaves differently because it produces a sterile residual immunity while the other two are followed by premunition. This worker stated that the endoglobular parasites and the intra-lymphocytic schizonts gave rise to distinct antibodies, and that after recovery from an endoglobular infection, the animal was still susceptible to the tissue forms, which were finally destroyed by lytic antibodies.

Immunity in trypanosomiasis was discussed in four papers. B. Weitz described his recent researches on exo-antigens in infections with the African trypanosomes. K. N. Brown analysed the antigens of *T. rhodesiense*, a highly labile organism which resorts to many changes in antigenicity, though reverting to the parent type after passage through *Glossina*. Two groups of antigens can be distinguished chemically by starch-gel electrophoresis and by ultracentrifugation ; one type is predominantly protein, the other is of unknown composition. This chemical approach has scarcely gone far enough yet for conclusions or principles to be drawn, but it offers promise for the future, especially when combined with the agar techniques using double diffusion of separating strains. A paper by M. A. Soltys and C. S. Folkers was presented by the latter and dealt with the effect of immunity on chemotherapy and chemoprophylaxis of the African trypanosomes of veterinary importance.

Two papers were given on toxoplasmosis. The first, by J. D. Fulton, gave a useful summary of the immunity reactions in this disease, and included details of the author's new agglutination test, using washed organisms from mouse peritoneal fluid. The results of this test corresponded closely with those of the Sabin–Feldman reaction, were constant, easy to read, and beset with none of the difficulties of the dye test. C. P. Beattie discussed the prevalence of the infection throughout the world in man, in other mammals and birds; but *Toxoplasma gondii* is a well-adapted parasite which rarely causes much pathogenicity to its host, either because most strains are of naturally low virulence or because of some special insusceptibility of the host. Youth, concomitant illness, and physical stress are factors which predispose to multiplication of the organism. Although several antibodies have been shown to exist in chronic infections, it is strange that none is particularly adequate in destroying the organism, perhaps because it eventually becomes enclosed in a cyst with an impermeable wall. But man has a natural resistance to the infection, which may be of the nature of premunition, the organism persisting in a latent form for years, and resembling in this and other aspects the tubercle bacillus.

Saul Adler described immunity in leishmaniasis, and discussed chiefly the reaction of man to the various cutaneous forms of *Leishmania*. He made a plea for the recognition and separation of these organisms into sub-species, of which there were two in the Old World and at least four in Latin America, causing the classical espundia in Brazil, uta in Peru, chiclero's disease in Central America and a curious form in Venezuela. These were distinct clinical entities, had special sandfly vectors, particular animal reservoirs, characteristic response to drugs and specific antibody reactions by which each form could be distinguished readily. He directed attention to the paradox of a protozoon making its home in cells of the lymphoid-macrophage system, the system which, *par excellence*, protects the host from protozoal infections. Nevertheless the host wins, and a persistent sterile immunity is the result.

Adler's paper formed a good introduction to the last part of the symposium, which concerned parasites localized in the skin or mucous membranes. The immunity reactions of this group have a peculiarly focal restriction, in contrast to the ordinary antibody response when the infection is generalized; but the difference disappears if these localized parasites are introduced artificially into the blood stream of the host, when a typical antibody reaction is the result. Muriel Robertson showed, however, that such antibodies, produced in response to *Trichomonas foetus*, were unable to reach the flagellates in their protected sites in the uterine wall; the production of antibody is a sequence of the presentation of antigen to the appropriate host cells; in trichomoniasis of cattle the antibody had a very limited value in destroying the infection.

C. Horton-Smith, P. L. Long, A. E. Pierce and M. E. Rose also examined the question of local immunity in coccidiosis and showed that a fowl which had recovered from an infection of *Eimeria tenella* in one cæcum was nevertheless immune in the other. These workers demonstrated that different stages of the life-cycle of coccidian parasites had their specific immunizing values. R. Augustin and A. P. Ridges. described similar work on *E. meleagrimitis* of turkeys.

In the early days, immunologists were much concerned in the practical aspects of cure or prophylaxis of disease: two papers in the present symposium show that this subject is still of interest to-day. S. Cohen and I. A. McGregor gave a most interesting account of the use of gamma-globulin in the cure of malaria. They collected sera from hyperimmune adults living in the Gambia and extracted the gamma-globulin component; this was then given in large doses to young children who were suffering from acute infections of the disease. Within 4 days, parasitæmia fell and by the ninth-day parasites were undetectable in 8 of the 12 cases studied. These investigations were accompanied by work on the turnover of gamma-globulin, on the lessening of hypergamma-globulinæmia as the result of specific therapy, etc., all of which observations tend to indicate that humoral immunity may be more important in malaria than was originally thought. The antibody appears to be contained in the 7-*S* fraction and not in the macroglobulin. P. E. C. Manson Bahr sent an important communication on a big field experiment he is carrying out in Kenya, in which he has immunized a population which is exposed to epidemic kala-azar with an avirulent ground squirrel strain of the organism. Preliminary work had shown that volunteers could be protected in this way.

The papers are being published in book form, and this should provide a modern review of many important aspects of the subject. P. C. C. Garnham

THE MUSEUMS ASSOCIATION

In the ideal environment of the City of Plymouth and its museums the sixty-seventh annual conference of the Museums Association was held during June 19–23, 1961.

The conference was officially welcomed by the Lord Mayor and this was followed by the presidential address by Dr. D. B. Harden (London Museum). In an interesting historical survey of the continual efforts of the Museums Association since 1945 to obtain Government grants for the provincial museums —and especially the smaller ones—he felt that there had been a certain amount of progress, for at last the Standing Commission for Museums and Art Galleries had been instructed to prepare a report. This was awaited with interest, though, meanwhile, the Association and museums throughout Britain were grateful to the Carnegie United Kingdom Trust for its continual help and advice. Reference was also made to the formation of the Area Councils and especially to the progress made by that in the south-west.

Sir Hugh Casson opened the discussion on display in museums, and in a provocative and entertaining address said that a lively imagination was necessary both in new buildings and in the adaptation of the older ones. He stressed that the building and display must be shared by the curator and the architect, and that it was essential to establish character and personality in a museum. A museum must be an active place—a lively cultural centre to arouse the sense of the curious.

Dr. D. A. Allan felt that the ideal display of natural history objects should include the clinical and the artistic. He also stressed the value of genuine objects, and said that it was important to achieve liveliness and realism. Large dioramas were not in the fashion at the present day. Mr. J. W. Y. Higgs (University of Oxford) dealt chiefly with folk material, and detailed the value of comparative displays—doing the same thing in different ways. He also referred to the need for more folk parks in Britain. Mr. Norman Cook (Guildhall Museum) stated that it was necessary to serve the public at different levels. He also felt that not all archæological exhibits should be treated as works of art, for it was not the curators' task to make everything look beautiful. As chairman of this session, Sir Frank Francis (British Museum) felt that there was no single solution to the problem of display for museums were both for the connoisseur and the ordinary visitor. The future may lie in some form of double exhibition.

A whole day was devoted to the many problems of conservation. Dr. P. Coremans (Brussels) opened the discussion, and said that great changes in the treatment of paintings was due to the scientific interest now taken in this subject. He described methods whereby it was possible to distinguish the layers of dirt, re-paint, varnish and the glazes which were an integral part of the picture itself. The extreme differences of opinion regarding restoration were also discussed. Mr. Norman Bronmelle (Victoria and Albert Museum) suggested a scheme for making modern scientific resources available to provincial museums, and Mr. H. Schubart (Bristol) spoke about the training of picture restorers. An art school basis was probably the best, but the creative impulse of the restorer must be directed entirely to conservation so that the welfare of the object became second nature.

An afternoon session was devoted to a symposium on modern developments of conservation in museums as opposed to art galleries. Dr. A. E. Werner

(Research Laboratory, British Museum) stressed the wider concept of conservation which involved successively preventive treatment, diagnosis of the causes of decay, research in the evaluation of new synthetic materials and scientific examination of the object before attempting treatment. Mr. H. W. M. Hodges (Institute of Archæology) said that at present there were only two academic training institutions in the world for conservators—in London and in New York. He detailed the training given in London and emphasized that conservation must be based on scientific knowledge. Mr. A. E. Rixon (British Museum (Natural History)) gave details of useful techniques for dealing with the preservation of fossils.

At the annual general meeting, Dr. Mary Woodall (Birmingham) was elected president for the ensuing year, and an invitation to hold the conference in Brussels in 1962 was accepted with gratitude.

Social events during the week included a civic reception and an annual dinner. At the end of the week organized tours to many of the museums and beauty spots in Devon and North Cornwall brought a memorable conference to a close.

DIGITAL COMPUTERS, THEIR USE AND CONTROL

A SYMPOSIUM on "Digital Computers, Their Use and Control" was organized by the Mathematics Department of Queen's College, University of St. Andrews, in collaboration with Standard Telephones and Cables, Ltd., during May 29–June 2. Standard Telephones and Cables, Ltd., provided the use of a *Stantec Zebra* computer for the whole course.

The first day was devoted to talks of a general nature to give a general appreciation of the use of computers. After an address of welcome by the Master of Queen's College, Prof. A. A. Matheson, Dr. R. J. Ord-Smith of Standard Telephones and Cables, Ltd., spoke on computer applications and this was followed by an address by Mr. W. A. Donaldson of Rolls Royce, Glasgow, entitled "Computers in Industry". The morning session was completed by a description of a transportation problem and its solution by Mr. W. A. E. Pillow of Standard Telephones and Cables, Ltd.

In the afternoon the symposium split into two sections. Those who wished to attend the whole course were given a demonstration of *Zebra* programmes and the remainder were given a brief introduction to programming.

The first day was attended by about eighty people of whom about thirty-five were from local industry and commerce and the remainder from the University. On subsequent days, about fifty people attended of whom ten were from outside the University.

The lectures on the remaining days were given largely by Dr. R. J. Ord-Smith and Mr. A. Y. Cooper of Standard Telephones and Cables, Ltd. They covered a comprehensive use of the *Zebra* simple code and an introduction to normal code. A lecture on "The Computer in the University" was given by Dr. A. J. Cole of Queen's College. By the end of the week, all delegates had written and run several programmes.

The members of Queen's College staff are grateful to Standard Telephones and Cables, Ltd., for providing such excellent facilities and in particular for the continued loan of a *Zebra* computer, which, in the week subsequent to the course had been in continual use for 8 hr. a day.

A NEW APPROACH TO BIOLOGY TEACHING

A CONFERENCE, proposed and financed by the Gulbenkian Foundation, was held in the University of Birmingham during April 10–12, to discuss the biology syllabus for sixth forms, proposed by the Biology Panel of the Gulbenkian Enquiry 1959*. The conference was attended by seventy-five schoolteachers and several lecturers from teacher-training colleges. The majority of the members came from the West Midlands. Several topics were selected from the syllabus and a lecture was given on each.

During his introductory lecture Prof. O. E. Lowenstein pointed out that the University of Birmingham will be offering a new type of biological training in the near future. This will consist of an honours B.Sc. degree in biological sciences. Undergraduates will take a variety of biological courses which will cut across the traditional subject-boundaries and be in closer accord with the trends in modern biology in pure and applied research, in industry, in agriculture, etc. Various subject-combinations will be possible. It is anticipated that fewer students will complete courses of the traditional type leading to a degree in zoology or botany, although it will still be possible to specialize in selected branches of biology, for example, systematic botany, entomology, etc. It is difficult to predict whether other universities will adopt similar schemes; but the wind of change is blowing in this direction and during recent years in many university departments, even within the traditional courses of zoology and botany, the subject-matter has changed dramatically. Already in Birmingham the preliminary (= intermediate) course in biology has ceased to be virtually separate courses in botany and zoology and is now a closely integrated course following the lines recommended in the Gulbenkian Report.

It is against such a background of a rapidly evolving subject that this new approach to biology in sixth forms is presented.

During discussion there emerged considerable agreement on the need for a new approach, both to teaching and to examining, of the type put forward in the Gulbenkian syllabus, although it was recognized that there would be various difficulties in implementing the recommendations of the report. It was suggested that a first step in the right direction would be to persuade the Northern Universities Joint Matriculation Board to set up a pilot scheme to give the new syllabus a 'field trial'. The chairman was instructed to write to the Board and make this proposal. He was also asked to produce a memorandum listing a number of specific difficulties involved in teaching biology and to circulate the memorandum to the Institute of Biology, local education authorities and other bodies who might be interested.

---

* Copies can be obtained from the Registrar, The University, Birmingham 15.

The points which emerged during the discussion were as follows: (1) Lack of exclusive use of biology laboratories by many teachers. This makes adequate preparation for practical work very difficult or impossible. It also makes difficult the keeping of cultures, aquaria, etc. (2) Lack of time for collection of material and preparation for practical work. (3) Lack of technical assistance. (4) Lack of preparation rooms and storage facilities. (5) Lack of transport for collecting and field work. (6) Inadequate grants for the purchase of material, books and equipment, such as physiological apparatus, stereoscopic microscopes, phase-contrast microscopes, aquaria, cages, incubators, ovens, refrigerators, deep freezers, etc. These items include essential basic equipment for the proper study of biology. (7) It was recognized that staffing and salary problems might arise if zoology and botany were replaced by a single biology.

It is relevant to all these items that the conference was agreed that teachers of biology require more time for the collection of material and the preparation for practical work than teachers of most, if not all, other subjects. Many teachers at the present time have to 'make do' in the face of considerable difficulties. The adoption of a syllabus like that proposed would increase these difficulties. The problems involved in the day-to-day teaching of biology in schools require objective study. There is no logical foundation for the assumption that every science subject requires the same number of teaching-hours for its presentation. L. H. FINLAYSON

SCIENCE AND EDUCATION : THE TEACHERS' POINT OF VIEW

A POLICY Statement, "Science and Education"*, issued by the Science Masters' Association and the Association of Women Science Teachers, revises the preliminary statement published by the Science Masters' Association in 1957. The Statement is accompanied by separate syllabuses on chemistry, physics and biology for grammar schools compiled by panels of the Science and Education Committee for these subjects and amended in the light of comments received. The Policy Statement now issued concerns mainly grammar schools and represents the first part of the promised report. The second part will include a scheme for the general study of science in the sixth form, and two other panels are concerned with the training of teachers and with new experimental work necessary for teaching modern physical science.

The present 'scientific illiteracy' is attributed partly to a lack of factual knowledge but much more to a lack of understanding of the basic nature and aims of science. Science should be recognized and taught as a major human activity which explores the realm of human experience, maps it methodically but also imaginatively, and, by disciplined speculation, creates a coherent system of knowledge. As a human quest for truth, it is much concerned with basic values and is indeed an active humanity, and it follows that schools have the duty of presenting science as part of our cultural and humanistic heritage, to be taught in harmony with, not in opposition to, the various arts subjects which alone have hitherto been called humanities. The Committee recognizes that an adequate supply of scientists and technologists is needed and believes that its recommendations will help to meet that need, but it stresses the cultural aim because science has not yet been given its proper place in general education.

It may be apposite in these pages to comment how Sir Richard Gregory, with his passionate belief in the cultural value of science, would have welcomed such a statement from such a source. To ensure that science is a 'core' subject in grammar schools, as English and mathematics now are and as classics used to be, the Committee recommends that *all* pupils should follow a balanced course of science subjects up to the end of their fifth form year, and this course should lie within the range of a group of natural sciences, each of which is concerned with a limited aspect of human experience, though it is essential that this formal course, mainly involving the sciences of biology, chemistry and physics, with some astronomy and geology, if possible, should help pupils to appreciate the wider range of science as a whole. There should be no division into science specialists and arts specialists until beyond this level, though the Committee recommends that subject specialization should be retained in the sixth form but with a reduction of the detailed factual content of the Advanced Level syllabuses for the General Certificate of Education.

Such a reduction should release time for the broader course of science which the Committee recommends should be studied by all pupils in the sixth form, a course which would enable pupils to attain the scientific literacy described as 'numeracy' in the Crowther Report. The implications of these three general recommendations are outlined in the remainder of the Statement which describes, first, the introductory phase covering approximately the first two years of a grammar school course; secondly, an intermediate plan, usually three years up to about sixteen, when the Ordinary Level examination for the General Certificate of Education may be taken; and, thirdly, an advanced (sixth form) plan, offering a course indicated for all students and a course for the science specialists. These are further amplified in the three accompanying sections dealing, respectively, with chemistry, biology and physics, which set forth a syllabus which might appropriately meet the needs of all three phases of the proposed policy. The syllabuses seem well designed to meet some of the criticisms which have been made of the outlook of science graduates themselves, and the Statement and its accompanying detailed sections demonstrate that the two Associations are tackling the revision of syllabuses imaginatively as well as energetically. They are to be commended not simply to the attention of science teachers themselves but at least as much to scientists and the professional associations, as well as to the universities, for the recommendations can scarcely achieve their full effort without full co-operation by the universities and professional bodies. Moreover, considering the steps already taken by the National Science Foundation in the United States, and in view of the serious shortage of science teachers both the Minister of Education and the Minister for Science should be considering the wider implications, and the steps that will be required at a higher level if the recommendations are to be adopted not merely in grammar schools but also elsewhere.

ATOMIC RADIATIONS AND LIVING ORGANISMS

SINCE 1955 various committees appointed by the U.S. National Academy of Sciences—National Research Council have been conducting a continuing appraisal of the effects of atomic radiations on living organisms. Various reports have come from sub-committees of the Committee on Pathologic Effects, and differ considerably in their approach and content[1].

The most generally valuable of the recent reports is that on *Inhaled Radioactive Particles* (ref. 1*a*). It contains, or provides references to, basic factual information on the nature of these particles, and the physiological and pathological mechanisms involved in their deposition in and translocation from the respiratory tract. The formidable complexity of the problems involved is clear.

Different processes are responsible for the retention of particles of different sizes and densities, and in practical situations the amount of radioactivity in a given particle is independent of the nature of the radioactivity and of the size of the particle. The rate of loss of radioactivity from particles deposited in the respiratory tract is not simply related to 'solubility' in body fluids. The problems of assessing radiation 'dose' to the tissue around a radioactive particle go to the root of what is meant by tissue dose, a concept which still awaits a fruitful synthesis of physical chemistry, cell biology and pathology, at least in relation to carcinogenesis. Although miners of radioactive ores have suffered a gross excess of cancer of the lung for several centuries, the relative importance of the different factors which may be concerned, including those non-radiative, is quite obscure.

Another report (ref. 1*b*) entitled *Long-Term Effects of Ionizing Radiations from External Sources*, is more discursive and covers the same ground as many fairly recent reviews: life-shortening, tumour production, cataract, fertility and ageing. Seven of the eleven sub-committee members come from the same university, five from the same department, and it is not unfair to say that this common background permeates the theoretical framework or point of view. The implication that ovarian damage in the adult human female is not irreversible (p. 27) would not be generally acceptable. The definition of threshold dose as a description of the possible response of a single animal (p. 2) seems likely to add further confusion to the existing conceptual muddle.

A short report (ref. 1c) on the *Effects of Ionizing Radiation on the Human Haematopoietic System* has also been issued, but much that is new is an expression of opinion, for example, on the proper clinical treatment for an individual exposed to a dose in the acutely lethal range. Routine blood counts at periodic intervals in occupationally exposed persons are "wasteful and unproductive in detecting low-dose radiation effects". When decisions are to be made involving exposure of populations, *society* must weigh the benefits against the potential health hazard (my italics).

SLOW DECOMPOSITION OF EXPLOSIVE CRYSTALS AND THEIR DAMAGE BY FISSION FRAGMENTS

By Dr. F. P. BOWDEN, C.B.E., F.R.S., and H. M. MONTAGU-POLLOCK
Physics and Chemistry of Solids, Cavendish Laboratory, Cambridge

Thermal Decomposition

WITH many explosive solids the decomposition may begin slowly before it passes over into rapid explosion or detonation. The onset of explosions is usually governed by thermal considerations: if the rate of heat liberated by the slow chemical decomposition of the crystal is greater than that of heat lost by conduction, the reaction will accelerate to explosion[1]. The mechanism of slow decomposition is therefore of considerable importance in determining the explosive process. We have in this Laboratory been using electron microscopy and electron diffraction to study the early stages of the slow decomposition[2-5].

Similar methods have also been applied to non-explosive crystals[6,7]. In the earlier work on explosive crystals, replica techniques or the scanning electron microscope were used. More recently we have been using direct transmission electron microscopy—which reveals more detail—to study both thermal decomposition and the decomposition produced by fission fragments. Silver cyanamide (Ag_2CN_2) was the crystal chosen for this work. Although it is explosive it was found to be stable in electron beams of moderate intensity, and the crystals could be grown thin enough (about 100 molecules thick) to be observed in transmission. The main products of decomposition at low temperatures are silver, carbon and gaseous nitrogen. The formation, movement and aggregation of the liberated silver can be followed in some detail.

The crystals were heated in a furnace *in vacuo* under controlled conditions at temperatures ranging from 150° to 350° C. and then placed in the microscope for observation. They were supported on carbon films lying on the specimen grids. Diffraction patterns of selected areas were taken in order to identify undecomposed and decomposed material. As well as qualitative information on the decomposition process, rough measurements of rates of decomposition were obtained from estimates of the volume of silver liberated, with the help of metal shadowing.

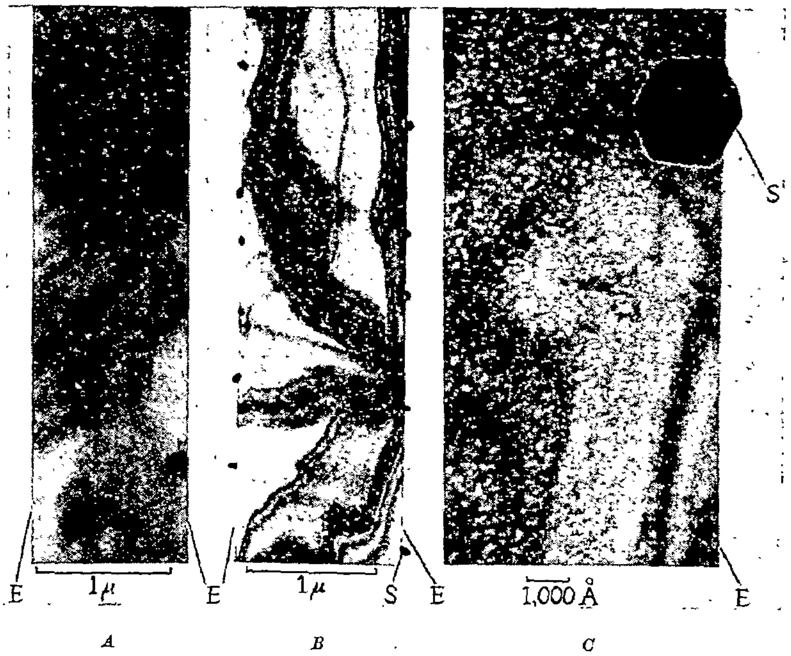

Fig. 1*A*. Symbols: *E*, true edge of crystal; *S*, silver aggregate. Undecomposed silver cyanamide crystal, about 200 Å. thick. The only visible details are the Bragg extinction contours, arising from slight elastic distortion of the crystal

Fig. 1*B*. Crystal in the first stage of thermal decomposition. A layer of the crystal extending from the surface to a depth of about 15 Å. has decomposed. The silver produced has diffused over the crystal surface and formed a few opaque specks at the the edges

Fig. 1*C*. Crystal in the second stage of thermal decomposition. Surface mobility of the silver is again apparent, with no evidence for nucleation of decomposition at the silver specks. Note the sharply bounded region of surface mottling

Fig. 1*A* shows an undecomposed crystal of silver cyanamide. Such crystals gave diffraction patterns consistent with the (100) orientation of the structure of silver cyanamide as determined by X-ray methods: this work will be described elsewhere and gives a monoclinic unit cell containing four molecules, with $a = 7{\cdot}26$, $b = 5{\cdot}92$ and $c = 6{\cdot}61$ Å., and with $\beta = 102°\ 20'$. The space group is $P2_1/c$.

Fig. 1*B* shows a crystal which has been heated for 2 min. at 200° C. A number of opaque specks can be seen at the edge of the crystal. Electron diffraction measurements show that these are single crystals of silver of random orientation. It would seem that the liberated silver is highly mobile and can migrate over the surface to sites of high surface energy on the crystal. These are frequently at the edge but may be elsewhere. These silver specks normally project from the crystal surface and, as they grow, develop more or less well-defined crystallographic faces (Fig. 1*C*); occasionally whiskers are seen. Nucleation, in the sense of decomposition spreading outwards from certain points, is never observed. Instead, the silver is liberated by an overall surface decomposition, before diffusing to the aggregation sites; this was deduced from plots of volume of silver per unit surface area of crystals against time at various temperatures, and confirmed by the observation that thermal decomposition was inhibited almost entirely if the crystals had previously been coated with a thin layer of carbon, evaporated on to the surface *in vacuo*. If the heating is continued for a sufficient length of time, the crystal is completely decomposed into crystalline silver and an amorphous layer which gives a diffraction pattern similar to that given by amorphous carbon (the possibility that some of this amorphous material may be formed by the polymerization of cyanogen[8] is not ruled out).

At temperatures below 230° C. the decomposition is found to take place in two stages. The first stage involves a progressive thinning of the crystal: the rate of this is of course dependent on temperature, and at 170° C., for example, it is about 0·7 Å./min. When the crystal has grown thinner by about 20 Å. (5 atomic layers), a second and much slower stage of the decomposition sets in. The thinning of the crystal continues at this stage until the crystal is completely decomposed, but the rate is about one-tenth of that observed in the first stage, for example, about 0·07 Å./min. at 170° C. It is possible that amorphous carbon formed during the first stage is responsible for the slowing down of the decomposition at the beginning of the second stage. As the decomposition proceeds, a mottling becomes visible, suggesting that the crystal surface is developing pits about 130 Å. in diameter, and consistent with the random surface decomposition process. The crystal in Fig. 1*C* is at this stage, and shows a characteristic often seen: the central part of the crystal is much more decomposed than the parts near the edges, where the mottling has not yet begun. The lines dividing these regions are perfectly straight, and there is evidence from other experiments that they may be associated with steps on the surface of the original undecomposed crystals.

If the crystals are heated in the presence of oxygen, an additional type of decomposition is observed:

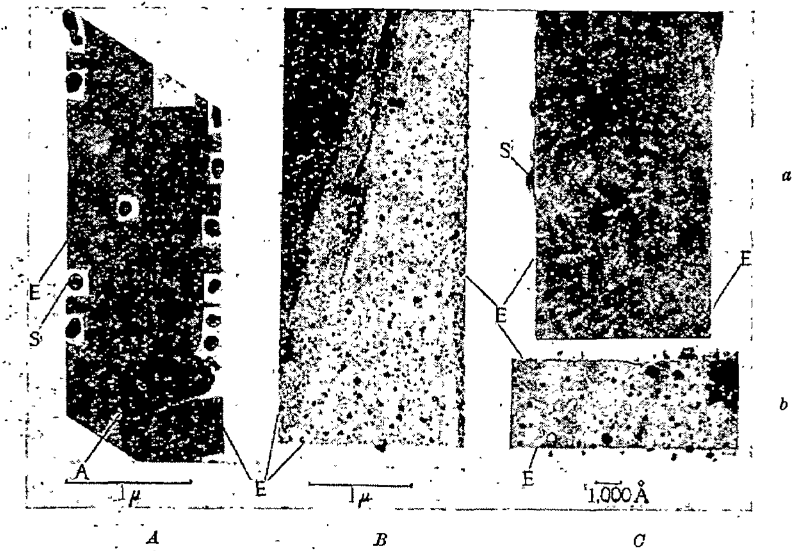

Fig. 2A. Crystal heated in the presence of oxygen. Additional decomposition takes the form of holes of crystallographic shape, starting around each silver speck and continuing to grow when isolated from it. Silver liberated by the growth of the holes has diffused over the crystal surface to aggregate at *A*

Fig. 2B. Crystal partially decomposed by the combined effects of heat and electron irradiation. A large number of specks of silver has appeared

Fig. 2C. (*a*) Crystal irradiated with uranium fission fragments (neutron flux density of $4\cdot3 \times 10^{15}$ n.v.t.). Each light area is a tunnel where material has been decomposed by a fragment: the dark areas are aggregated silver. (*b*) Crystal similarly irradiated (at a lower neutron flux density, $7\cdot2 \times 10^{13}$ n.v.t.)

the silver specks formed during the first and second stages cause the crystal to decompose through its whole thickness in their immediate neighbourhood, so that a hole appears around each speck (Fig. 2*A*). These holes rapidly take on crystallographic shapes and grow at a constant rate. The holes first become visible during the second stage, when the rate of growth of a silver speck is overtaken by the rate of growth of a hole. The liberated silver tends to diffuse over the crystal surface as before, rather than enlarge the new isolated silver specks. It aggregates at one or two specific sites.

If the electron beam intensity in the microscope is raised above a critical value, decomposition of the crystal occurs in the microscope. Under these conditions the liberated silver forms a large number of small specks distributed over the surface of the crystal (Fig. 2*B*). A similar distribution of the silver is obtained if the crystal is heated in a furnace to a higher temperature ($>$ 300° C.). If the beam intensity is raised still higher the crystal explodes giving silver and amorphous carbon. Heating to a high temperature will produce a similar explosion. If a cold stage is used in the microscope, the decomposition in the electron beam is inhibited. This behaviour is consistent with the view that the main effect of the intense electron beam is to heat the crystal to a high temperature.

Decomposition by Fission Fragments

Earlier experiments have shown that (with certain exceptions, such as nitrogen iodide) most explosive crystals do not explode when irradiated with a moderate intensity of neutrons or fission fragments[1]. Important changes are, however, produced and the explosive may be rendered more sensitive to subsequent thermal decomposition.

A study has been made in the microscope of the damage and of the tracks produced in silver cyanamide when it has been bombarded by uranium fission fragments. The damage of inert materials such as mica[9,10] and uranium oxide[11,12] has been described by others.

An experimental method developed by L. T. Chadderton of this Laboratory was used: silver cyanamide crystals in contact with thin foils of natural uranium were irradiated in the Harwell *Bepo* reactor for periods of 1 min.–10 hr. at a pile factor of 12. The grids were then examined by transmission electron microscopy as described above.

Fig. 2*C* shows a typical result of the irradiation. The light dashes and dots show that where each fragment has penetrated the crystal, material has evaporated or diffused away. The longest tracks represent paths of fragments travelling almost in the plane of the crystal, while dots indicate fragments that penetrated the crystal vertically. The mean track diameter is about 120 Å. The silver originally present in the volume occupied by a track has invariably diffused away from the track. On a few micrographs, an occasional fragment is seen to have caused greater damage than usual.

The greater part of the heat liberated by the passage of a fission fragment through a solid is due to ionization. Taking rough values of range and initial energy of a fragment in silver cyanamide to be 30μ and 80 MeV., the energy released is about 300 eV./Å. along a track. With the observed track radius of 60 Å., this gives a figure of about 650° C. (reached in about 5×10^{-11} sec.) for the maximum temperature of a molecule at the wall of a track. This implies that this is the maximum instantaneous temperature that a molecule can reach without decomposing: but the figure of 650° C. is necessarily very crude, because of the assumptions made in the calculation. However, the width of each light area is greater than in the inert materials, indicating that the damage is greater when additional heat is liberated by the decomposition of the material. This heat is of the same order as the heat supplied by the passage of the fragment, per unit length of track. It is not enough to produce explosion; this is consistent with estimates of limiting hot-spot sizes (10^3–10^5 Å.) for a number of explosives (see ref. 13 for further discussion).

The silver produced by the decomposition, in diffusing away from the sites where it is liberated, shows the same high mobility of the silver released from the crystals heated in the furnace.

Conclusion

The thermal decomposition studies have shown the importance of direct observation in investigating the physical processes involved. Nucleation at the interface between parent crystal and solid decomposition product has been observed only in the special case involving the initiation of holes of crystallographic shape. In general, the decomposition has been shown to take place everywhere on the crystal surface; and there is a suggestion that surface steps have some influence on the decomposition. The silver produced by the decomposition is very mobile on the crystal surface. The study of fission fragment tracks shows that this mobility applies also to silver liberated within the body of the crystal. It also confirms the earlier conclusion that the 'hot-spots' or 'hot cylinders' produced by fission fragments are too small to initiate explosion.

TERNARY COMPOUND FORMATION IN THE SYSTEM $CaO-Al_2O_3-MgO$

By J. H. WELCH

Building Research Station, Garston, Watford, Hertfordshire

THE quaternary system $CaO-Al_2O_3-SiO_2-MgO$ has been studied extensively at high temperatures because phase equilibria in this system provide basic knowledge of importance in understanding geological and industrial processes. Of the four ternary planes bounding the quaternary volume, the $CaO-Al_2O_3-MgO$ system is unique since its original and only investigators to date[1] found no evidence of ternary compound formation. Possibly, because of the apparently simple nature of the system and also its lack of geological significance, its long-established phase diagram has never been questioned. The system is, however, of considerable importance in understanding the potential compound formation in high-alumina cement, and work in this connexion has led to the discovery of two ternary compounds having the approximate compositions $7CaO.5Al_2O_3.MgO$ and $25CaO.17Al_2O_3.8MgO$.

The discovery of these compounds arose from the reported existence[2] of a quaternary compound, the composition of which was believed to be $6CaO.4Al_2O_3.MgO.SiO_2$. Attempts to confirm this reported formula were unsuccessful and led to an extensive investigation of adjoining compositions. In the course of this work, high-temperature microscope observations revealed that a homogeneous compound of composition $7CaO.5Al_2O_3.MgO$ could be prepared having optical and X-ray properties similar to those of the alleged quaternary compound. Since then, further work has disclosed that this ternary compound may be metastable at all temperatures, and is certainly so at temperatures above the solidus of the ternary system (1,344·5° C.) since it is observed to melt at 1,332° C. Its significance, however, resides in its solid-solution behaviour in the presence of silica. Preliminary observations suggest that a discontinuous series of solid solutions exist between $7CaO.5Al_2O_3.MgO$ and the compound gehlenite, $2CaO.Al_2O_3.SiO_2$. With increasing gehlenite content, these solid solutions first melt incongruently to yield a melt of $CaO.Al_2O_3$ and liquid, but congruent melting is established for compositions exceeding 40 per cent by weight gehlenite. It seems, therefore, that the quaternary compound reported might be accounted for as one of a series of solid solutions between two ternary compounds.

Following the initial discovery of the $7CaO.5Al_2O_3.MgO$ compound, a search was made in the system $CaO-Al_2O_3-MgO$ for a possible new primary phase field. Such a field was in fact located approximately by high-temperature microscopy and this was followed by a very precise quenching study of the indicated region. From a consideration of the course of crystallization of several of the compositions studied it became apparent that the very small primary phase field, which had been demarcated, could not be related to the $7CaO.5Al_2O_3.MgO$ compound.

It followed that a second ternary compound must exist in the system which bore a remarkable physical resemblance to the first. The two compounds in fact possess optical properties which are so similar that they cannot readily be distinguished by microscopic examination, although fortunately their X-ray diffraction patterns are quite distinct. The composition $3CaO.2Al_2O_3.MgO$ was at first assigned to the second of the two ternary compounds, but further examination of crystallization paths and homogeneity indicates that the almost contiguous and more complex composition $25CaO.17Al_2O_3.8MgO$ is more certainly correct. The similarity of optical properties suggested that there might be some solid-solution relationship between the two ternary compounds, but their separate co-existence has been checked by X-ray examination. As both compounds decompose on melting, their preparation in pure form presents considerable difficulty.

The 25 : 17 : 8 compound can be prepared in bulk by complete fusion at 1,650° C., followed by annealing of the rapidly chilled liquid at 1,200° C. Even with this treatment, several attempts may be necessary to suppress the formation of some magnesium oxide which, as the primary phase for this composition, tends to precipitate rather readily from the liquid. All similar attempts at bulk preparation of the 7: 5: 1 compound have failed; such heat-treatments

Table 1. PHASE DATA

$7CaO.5Al_2O_3.MgO$: Melts at 1,332° C.; may be metastable below this temperature with respect to $CaO.Al_2O_3$, $12CaO.7Al_2O_3$, and MgO.

$25CaO.17Al_2O_3.8MgO$: Melts incongruently at 1,350·5° C. with formation of $CaO.Al_2O_3$, MgO and liquid. Primary phase field terminates at:

(1) Reaction point; temperature 1,350·5° C. Equilibrium phases: $25CaO.17Al_2O_3.8MgO$, $CaO.Al_2O_3$, MgO and liquid. Composition (weight per cent): 42·6 CaO, 51·3 Al_2O_3, 6·1 MgO.

(2) Eutectic; temperature 1,346° C. Equilibrium phases: $25CaO.17Al_2O_3.8MgO$, $12CaO.7Al_2O_3$, MgO and liquid. Composition (weight per cent): 44·4 CaO, 49·9 Al_2O_3, 5·7 MgO.

(3) Eutectic; temperature 1,344·5° C. Equilibrium phases: $25CaO.17Al_2O_3.8MgO$, $12CaO.7Al_2O_3$, $CaO.Al_2O_3$ and liquid. Composition (weight per cent): 43·8 CaO, 50·9 Al_2O_3, 5·3 MgO.

Table 2. OPTICAL DATA

Composition	Refractive index (sodium light)	Birefringence	Optical character	Habit
$7CaO.5Al_2O_3.MgO$	$\alpha = 1·671$ $\gamma = 1·674$	Weak anomalous interference	Biaxial negative	Lamellar
$25CaO.17Al_2O_3.8MgO$	$\alpha = 1·675$ $\gamma = 1·678$			

have yielded a mixture of the 25 : 17 : 8 compound, $CaO.Al_2O_3$, and either $12CaO.7Al_2O_3$ or 'unstable $5CaO.3Al_2O_3$'. The latter compound has at various times been confused with the alleged quaternary compound $6CaO.4Al_2O_3.MgO.SiO_2$, but its separate existence has previously been established[3].

The 7 : 5 : 1 compound has only been isolated in minute quantity by carefully controlled supercooling of the melt conducted under continuous observation with the high-temperature microscope. Even by this technique it is only with the greatest difficulty that it has been found possible to grow single crystals of the compound, which exhibits a marked lamellar habit. The majority of compositions being studied at present in the hypothetical solid-solution series $7CaO.5Al_2O_3.MgO - 2CaO.Al_2O_3.SiO_2$ are, however, susceptible to bulk preparation by the method described.

Table 3. X-RAY POWDER DATA

Because of limitations on space, only the principal X-ray spacings for the two compounds are given here. Full powder-diffraction data are available on private application. The *d*-values here as *VS* (very strong), *S* (strong), *M* (medium) were obtained from measurements in a Guinier-type focusing camera, 114 mm. diameter, with copper *Kα* radiation

Although I hope to publish a more complete description of this work eventually, it seems desirable to present a summary of the available information which is given in Tables 1, 2 and 3.

This information may be particularly useful if it is found that analogous ternary compounds exist in which FeO substitutes for MgO and Fe_2O_3 for Al_2O_3, as seems not unlikely.

This work is subject to Crown copyright.

FORMATION OF CHALCOPYRITE BY REACTION BETWEEN CHALCOCITE AND PYRRHOTITE IN COLD SOLUTION

By W. M. B. ROBERTS

Bureau of Mineral Resources, Geology and Geophysics, Canberra

THE simple metallic sulphides are readily precipitated from solution by the sulphide ion. These sulphides have also been precipitated from solutions by the action of sulphate-reducing bacteria[1].

Up to the present, however, the complex sulphides have been synthesized only at higher temperatures either by the reaction of elemental sulphur, copper and iron, or by solutions containing one or more of the constituents acting on the metals or their sulphides. Roy[2] showed that bornite situated along grain boundaries in pyrite changes to chalcopyrite when heated at 100–175° C. for 3–5 days. Park[3] carried out experiments on copper compounds—his work on sulphides was concerned with passing steam, steam and carbon dioxide, and steam and hydrogen sulphide over chalcopyrite and chalcocite. Schouten's[4] work involved the action of concentrated aqueous copper solutions on various sulphides, and showed that chalcopyrite can form in a few hours on marcasite, pyrite, and pyrrhotite at atmospheric pressure and at about 100° C.

Gill[5] quotes results using solid blocks of simple sulphides of iron and copper at temperatures ranging from 350° to 650° C. for periods of 3–48 hr. Bornite and chalcopyrite were formed.

The present attempts at the formation of the complex sulphide differ from the previous work in that they were carried out at room temperature, and that either distilled water or sea-water played a part in the reaction.

It was decided to attempt the formation of the complex sulphide in this manner when, during the

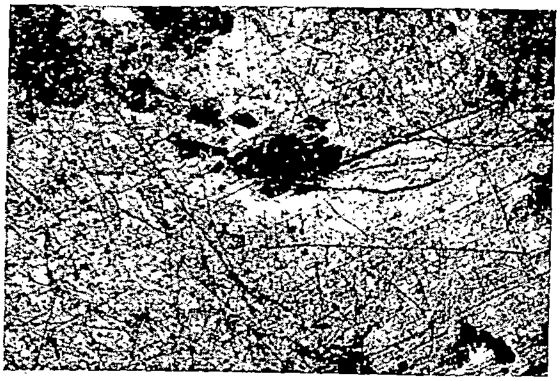

Fig. 1. Continuous coating of chalcopyrite on polished surface of chalcocite block (× 40)

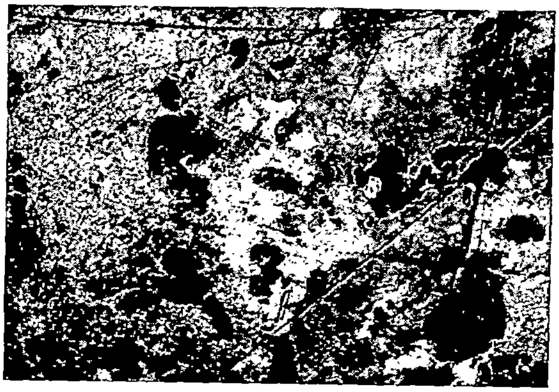

Fig. 2. Patchy coating of chalcopyrite on polished surface of chalcocite block. Chalcopyrite, dark grey; chalcocite, light grey (× 40)

course of preparation of blocks of sulphides for high-temperature synthesis, it was noted that, after about 5 min. contact between the wet ground faces of pyrrhotite (FeS) and chalcocite (Cu_2S), sufficient iron had been transferred to the chalcocite to give it a bronze colour on the ground surface. It was supposed that this iron had been removed from the surface of the FeS at an accelerated rate due to the presence of the water film at the interface, and that there was a possibility of a reaction with Cu_2S to form one of the copper iron sulphides.

Blocks about 1 mm. across were cut from naturally occurring chalcocite (Cu_2S), and pyrite (FeS_2), as well as from artificial pyrrhotite (FeS) made from iron filings and sulphur. A face was polished on these, and they were examined under an ore microscope to ensure that no other sulphides were present. Pairs of these minerals giving the combinations pyrrhotite–chalcocite and pyrite–chalcocite were held firmly together with their polished faces in contact, using clips made from heavy-gauge stainless steel wire.

A pyrrhotite–chalcocite and a pyrite–chalcocite pair were placed in a beaker of distilled water, and the same pairs placed in a beaker of artificial sea-water. Both beakers were allowed to stand at room temperature for five days. During this time it was observed that the pyrrhotite in both beakers formed a rim of hydrated iron oxide at the interface of the blocks within a few hours. After the first day a deposit of hydrated oxide was spread evenly over the bottom of both beakers. No apparent alteration took place on the exposed surface of the chalcocite blocks.

After five days the blocks were removed from their solutions and separated. The pyrite–chalcocite pairs in both sea-water and distilled water showed no reaction along the polished interface. The pyrrhotite–chalcocite pairs both had a brass-yellow deposit on the surface of the chalcocite. This deposit had covered the whole polished surface of the chalcocite from the distilled water (Fig. 1) but was patchy on the chalcocite from sea-water (Fig. 2).

In neither case was it found necessary to re-polish the chalcocite blocks for examination under the microscope; the new mineral had formed on the chalcocite, preserving the surface polish and scratches perfectly (Figs. 1 and 2). However, the surfaces of the pyrrhotite blocks had become etched, and had lost the original texture shown in the polished section (Figs. 3 and 4); but no new mineral had formed on their surfaces. The newly formed mineral was identified by X-ray diffraction as chalcopyrite ($CuFeS_2$). This mineral had not formed an intermediate layer between the two blocks—it had completely replaced part of the chalcocite; some of it had extended over the edges of the polished surfaces, along the sides of the chalcocite blocks. No other parts of the blocks exposed to the solutions showed any formation of chalcopyrite or any other change from the original material.

The depth of penetration of the chalcopyrite into the blocks of chalcocite was measured by cutting and polishing them in a plane normal to the polished surfaces. Microscopic examination at 1,100 magnifica-

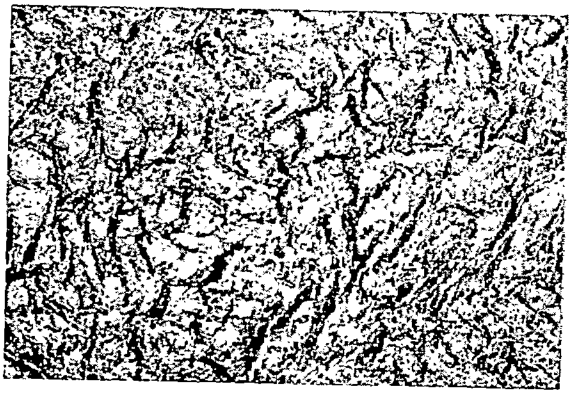

Fig. 3. Polished surface of pyrrhotite block before reaction (× 40)

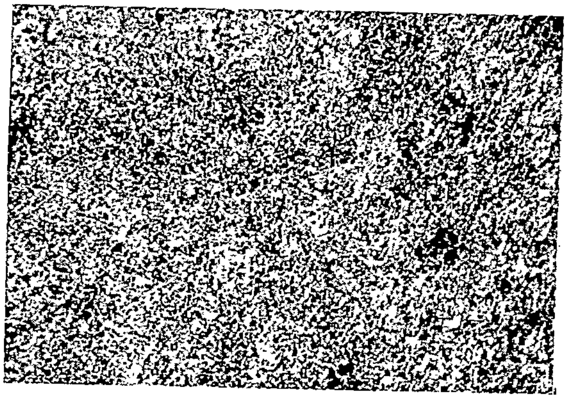

Fig. 4. Etched surface of pyrrhotite block after reaction (× 40)

tions showed that the penetration was highly irregular. It ranged from a sub-microscopic thickness to a depth of 0·11 mm. in the specimen placed in sea-water and to a depth of 0·13 mm. in that placed in distilled water. In one place chalcopyrite had formed to a depth of at least 1·5 mm. along a microscopic fracture.

It is of interest that, in these experiments, the iron moved into the copper sulphide, whereas Gill[5] found that the copper moved into the iron at a greater rate than the iron moved into the copper.

A block of chalcocite held in contact with a block of pyrrhotite for one month in an evacuated tube at room temperature showed a very faint brass-yellow tarnish on a small area of its surface, indicating that slight reaction had taken place even without the presence of a film of water between the blocks.

Some blocks of chalcocite were immersed in a cold solution containing ferrous ions, and another containing both ferrous and cupric ions, for ten days. No reaction was observed in any of the blocks. This seems to indicate that the reaction is not a result of general solution of iron from pyrrhotite and its subsequent reaction with chalcocite.

An electrolyte is evidently necessary for the reactions to proceed at a reasonable speed at room temperature. Both Cu_2S and FeS have very low solubilities:

Cu_2S, at 16° – 18° C.	2×10^{-47}
FeS, at 18° C.	$3{\cdot}7 \times 10^{-19}$

so that solution and recombination in the usual sense do not offer a reasonable explanation for the reaction because the quantity of $CuFeS_2$ is greater than could be expected to form from dissolved Cu_2S and FeS in the period involved in the experiment. Furthermore, a reaction was observed between Cu_2S and FeS even in the dry state. When the two sulphide blocks are brought into contact in water an electrolytic cell is formed, the e.m.f. of which, measured on a Cambridge *p*H meter, was found to be 0·51 V. This is responsible for the accelerated removal of Fe^{++} ions from the FeS and their transfer to the surface of the Cu_2S block to form the complex sulphide.

Both FeS and Cu_2S are capable of a high degree of non-stoichiometry. If non-stoichiometry is to persist in a crystal, electrical neutrality must be maintained—cation vacancies must be accompanied by a deficit of electrons to maintain neutrality—and therefore the degree of the non-stoichiometry is directly related to the diffusion properties as well as to the electronic properties of the crystals.

The behaviour of FeS in particular has been extensively studied, and it is known to be able to stand extreme departures from stoichiometry in the form of cation vacancies, without a change of phase. It would therefore be expected that where such great departures from stoichiometry are present they would be accompanied by a high diffusion constant.

Stone[6] has suggested a structure-sensitive diffusion by way of grain boundaries or Smekal cracks due to different mosaic structures in crystals. Barrer[7] gives some of the causes of this type of cracking in crystals along the surfaces of which diffusion can take place. As surface diffusion is much faster than volume diffusion it is possible that less activation energy is required for diffusion via cracks than via lattice vacancies.

Stone also suggests that the presence of impurities having different valencies from those of the normal crystal ions can have a marked effect in lowering the activation energy. If a divalent cation is substituted for a monovalent one in a crystal, electrical neutrality is maintained only by the formation of a cation vacancy. Cation vacancies of this type are present at all temperatures, and at the same concentration, and consequently their effect on diffusion will be much greater at lower temperatures at which there are fewer high-temperature vacancies.

The FeS used in this work is made up of randomly oriented small crystals the average size of which is 0·3 mm. The material has an irregular texture on the polished surface (Fig. 4), apparently the result of fractures developed during the cooling of an aggregate of anisotropic crystals. A semi-quantitative X-ray spectrographic analysis shows the impurities are: zinc, 0·5–1 per cent; copper, 0·1–0·5 per cent; lead, 0·1–0·3 per cent; arsenic, 0·05–0·1 per cent; manganese, 0·05–0·1 per cent; tin, trace; nickel, trace.

The Cu_2S used contains traces of nickel and iron as well as about 0·1–0·3 per cent bismuth. It is a polycrystalline aggregate having an average grain-size of about 0·6 mm. No cracks were observed on the polished surface at a magnification of 600, but the nature of the penetration of $CuFeS_2$ indicates that some diffusion has taken place along submicroscopic cracks as well as along grain boundaries.

The suggestions advanced by Stone suggest mechanisms by which low-temperature diffusion may take place. Both his conditions are fulfilled; these are the presence of impurities having a different valency and a large number of grain boundaries and fractures to act as channels for diffusion. In addition, the high degree of non-stoichiometry in these compounds enhances the possibility of diffusion at low temperature.

Once the iron has been removed from the FeS and brought to the surface of the Cu_2S, the complex sulphide will form because its lattice energy is greater than that of Cu_2S; the reaction goes in the direction where the free-energy change is negative.

Calculations of the unoccupied volume of the Cu_2S structure show that it has about 24 per cent unoccupied space compared with about 19 per cent for $CuFeS_2$. If the unoccupied volume bears an inverse relationship to the lattice energy, then it would be expected that $CuFeS_2$ would form at the expense of Cu_2S.

If this theory is valid, $CuFeS_2$ would form in preference to Cu_5FeS_4 (bornite), which has an unoccupied volume of about 23 per cent. Similarly its formation would be expected before the other copper–iron sulphides, cubanite ($CuFe_2S_3$) or valleriite ($Cu_3Fe_4S_9$), the unoccupied volumes of which are 22 and 41 per cent respectively.

I wish to thank Mr. L. L. Hawes of the Department of Chemistry, School of General Studies, Australian National University, for his helpful advice on some aspects of this work, and to acknowledge the help of G. J. G. Greaves, of the Bureau of Mineral Resources, in the study of the literature on sulphide synthesis. The photographs were taken by J. Zawartko, of the Bureau of Mineral Resources.

This work is published by permission of the Director, Bureau of Mineral Resources.

CRYSTALLIZATION KINETICS IN POLYVINYLCHLORIDE AND THERMOELASTIC RELAXATION INDUCED BY ULTRASONICS

By Dr. V. NARDI

Istituto Nazionale di Fisica Nucleare, Istituto di Fisica dell Università, Padova

It is still an open problem to determine with certainty the molecular characteristics governing the crystallization kinetics in long-chain polymers. The importance of different elements has been recognized, such as length of repeating unit in the chain, kind and dimension of lateral substituent groups, geometrical irregularity in which they can be placed along the chains, etc.[1]. As Kitaigorodski's work[2] on monomeric organic crystals suggests, the molecular packing efficiency also has to be considered. It may be negligible for molecules with a very awkward shape, and crystallization will not occur. The packing efficiency depends also on the stereochemical regularity of the molecules. On the other hand, it has been observed[1] that this efficiency can be lower in the regular arrangements for any shape of molecule, so that dearth of packing efficiency remains a not very convincing cause of failure to crystallize. Furthermore, there are polymers in which the chain carbon atom carries two lateral groups of different size, for example, polyvinyl alcohol (—CH_2CHOH—$)_n$, and these reach crystalline form easier than other polymers with the same deficiency in regularity of position, along the chain, of substituent atoms having almost equal size. Besides the approximate criterion requiring, in connexion with substituent group sizes, some geometrical regularity in their position in space, it is not possible to determine whether a long-chain polymer will crystallize at all, and if so, how readily.

It seems reasonable, therefore, that for polymers regarded as non-crystalline, the crystallization is not really impossible, but only the right conditions to crystallize are not found during the preparation of the material. I have used polyvinylchloride (—CH_2—$CHCl$—$)_n$ in the form of 500 per cent stretched fibre with high homogeneity characteristics (molecular weight approximately 60,000) in order to see whether the amount of crystalline material, normally very low (about 10 per cent before stretching, about 40 per cent after stretching in hot water and suddenly quenched), can still be increased in drawn material and in order to get information on the rate of this transformation.

In these fibres, assuming that crystallization is favoured especially by the parallel orientation of molecules induced by the drawing process, there is no reason to assume that chain folding is the normal case[3], and I shall not consider the presence of morphological structures like spherulites, the crystallinity comprising crystallites (or fringed micelles) embedded in the amorphous material and oriented with the carbon chains along the fibre axis. The fibre has been radiated with 1 Mc./s. ultrasonics for different time-intervals t and different temperatures T_B of the water-bath in which the samples were placed during the radiation. For an equal radiation time t, the greatest increase in crystallinity has been found at $T_B \simeq 90°$ C., that is, the temperature where attenuation measurements show a maximum in ultrasonic absorption by the polymer[4]. (I have not carried out systematic measurements above this temperature.)

In Fig. 1 the observed increase is plotted in percentage weight of crystalline material versus the radiation time t ($T_B = 90°$ C.) as measured by X-ray analysis. Detailed information has already been given[5,6] on these measurements and on appreciable effects on the mechanical and thermoelastic properties of fibre due to this increase in crystallinity[7].

I shall discuss here briefly what kind of useful information about the crystallization kinetics one can get from a knowledge of relaxation phenomena inside the fibre and from the growing modality of crystallite under ultrasonic radiation. Information and references concerning these phenomena in polycrystalline solid material are given in ref. 8. I should like to mention the importance of the thermoelastic relaxation at the frequency used here. At this frequency the molecular motions are taking place between the isothermal limit and the adiabatic limit, and flow of heat between adjacent crystallites arises from internal friction. The ultrasonic radiation induces strains which are macroscopically homogeneous ($\lambda_{us.} \simeq 0{\cdot}2$ cm.). The elastic anisotropy of single crystallites embedded in the amorphous material, and their irregular and discontinuous arrangement, present also in this case of strong orientation along the fibre axis, renders it almost impossible for these

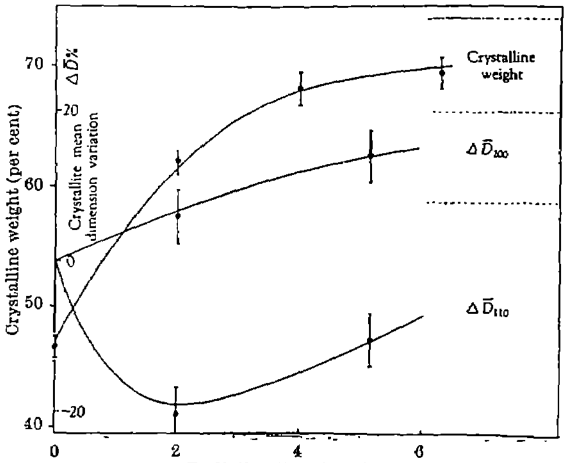

Fig. 1. Vertical axis left-hand scale gives crystalline weight per cent; the right-hand scale gives the change $\Delta\bar{D}$ per cent in mean crystallite dimensions $\bar{D}_{200}$ and $\bar{D}_{110}$, respectively, in the direction normal to the (200) and (110) planes, versus time of radiation. Dotted lines represent the limiting values for each quantity considered as obtained by fibre annealing and shrinkage at 150° C. in water

strains to be also microscopically homogeneous. Beside the flow of heat associated with these stress fluctuations, one has to consider also irreversible displacements in crystallite positions. These displacements can play a leading part in the crystallization process.

In order to account for the experimental observations on microscopic structure, one has to accept as true that inside the amorphous material many chain segments, all adjacent and already ordered parallel by stretching, have only a very low propensity to assume a packed configuration and consequently to crystallize. The reason for this, apart from molecular irregularity, is due I think to the fact that the movements of chain segments are hindered by the very low mobility of crystallites from which these segments ramify. The mutual distances between chain segments cannot be reduced by thermal oscillations, which do not affect the crystallite position sufficiently. From this description it seems clear why the 'effective' packing efficiency depends in a non-uniform way on regularity of chain structure, as the analysis of different polymers shows. In fact, some polymers may have, inside an amorphous region, almost parallel chain segments with quite regular structure and lateral groups of equal dimensions, but without the ability to move and, therefore, to form new nuclei, because of the very high friction associated with the smallest displacement of the binding crystallites. The chain segments will remain frozen in the positions assumed in the fibre production process, and crystallization will be arrested at low values for any interval of some limited time-scale of observation. In other polymers, also with different dimensions of lateral groups or some irregularity in their disposition along the chain, the friction for crystallite displacements may be very low, so that the relaxation processes bringing the chain segments to a close-packed configuration take place in a short time.

Accepting this picture, the ultrasonic action through change in local stress and temperature may be very relevant, as we have observed in polyvinylchloride. The rate of generation of new nuclei and their further growth strongly increase with the energy losses of the ultrasonic field. In polyvinylchloride the difference in substituent group dimensions is large (the Van der Waals's radii of hydrogen and chlorine atoms are respectively 1·10 Å. and 1·70 Å.). Atacticity, always present in a measure depending on the polymerization process used, may also prevent crystallization. On the other hand, the possibility of changing the degree of crystallinity to a very large extent, suggests that a more important element is the chain mobility and, therefore, the possibility for crystallites to realize irreversible displacements. This point of view is quite well supported by the experimental observation that, allowing the stretched polyvinylchloride fibres to recover their initial length in a thermal bath above the glassy transition temperature T_g, the amount of crystallinity may still increase up to 80 per cent in weight[6].

In Fig. 2 the general behaviour of the probability of nucleus generation, $P = \text{const.}\exp(-\Delta G/KT)$, is plotted versus temperature between the melting point T_m and the II-order temperature T_g. The width of the interval T_gS depends on chain mobility, strongly affecting the Gibbs free-energy variations ΔG. For chain segments inside the amorphous region, bound to not appreciably mobile crystallites, their mobility is very much reduced and the same applies to the probability of nucleus formation.

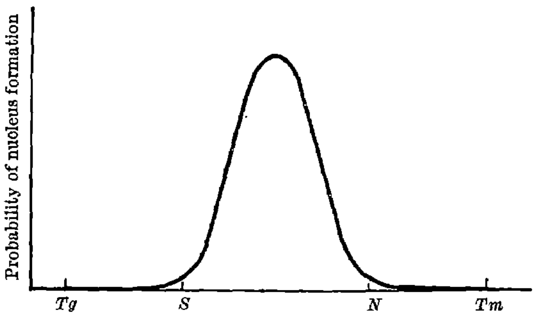

Fig. 2

Such a strong influence of very low crystallite mobility on that of the amorphous chain segments, which constitutes the essential point in the microscopic model assumed here, may also operate above T_g, where the polymer is in a rubber-like state, provided that the fibre has bounded ends, has been produced during ultrasonic radiation. In such a way fibre retraction is prevented; low mobility and strong orientation of chain segments in amorphous and crystalline regions are conserved. The thermoelastic relaxation induced by ultrasonics explains quite well the increase of crystallization with radiation time. If it is true that this relaxation governs the increase of crystallization with time, it becomes clear enough how the molecular characteristics can influence the crystallization process. They are essentially contributing to the same extent that the crystallite mobility and, consequently, that of the chains, is affected.

One has to observe that in the picture now presented, it is misleading to accept for the chain segments of the amorphous region, the possibility that all configurations consistent with the chain structure itself is approached. As a consequence, one has to change appreciably the evaluation of the configuration factor used in the Flory–Huggins theory and in the one-phase model of Frith and Tuckett[9], in order to determine the thermodynamic potentials.

In a general case, the generation of new nuclei may be described as taking place by two steps: in the first a parallel arrangement of chain segments is reached with high changes in entropy ΔS; in the second, the chains pack through small displacements, a monomer unit length at most, along their axis, in a configuration having a minimum internal energy U.

For stretched fibres, the parallel configuration is approached everywhere to a large extent, and the entropy contribution to the free-energy changes $\Delta F = \Delta U - T\Delta S$, originated by crystallization, is not appreciable ($\Delta S \simeq 0$). The increase in pressure and the relaxation phenomena induced by ultrasonics allow the energy barriers separating the amorphous from the crystalline configuration to be overcome. The possibility of new nuclei generated in already partially crystalline fibres must depend also on the extension of the amorphous regions, all interconnected, but approximately delimited by surrounding crystallites as set up in the stretching process. If the number of parallel chain segments in some of these regions is too low, no transformation of

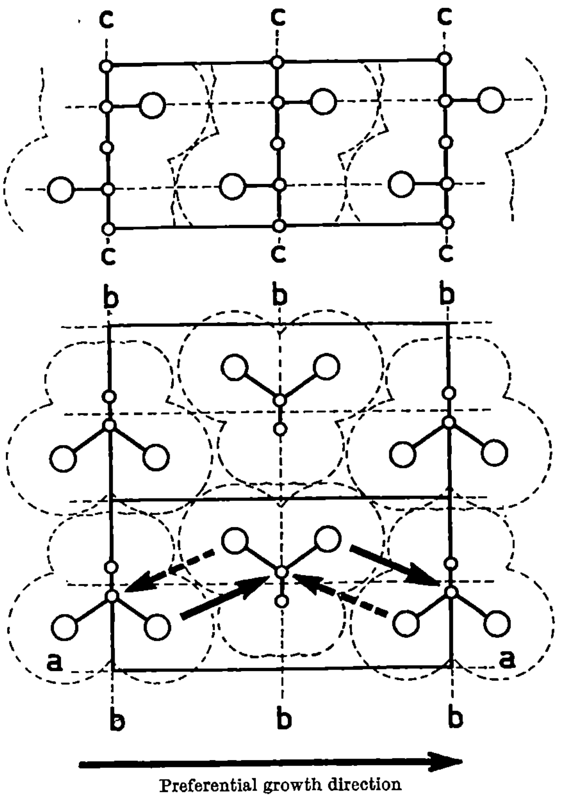

Fig. 3. Assumed crystalline structure with the axis $a = 10 \cdot 6 \pm 0 \cdot 1$, $b = 5 \cdot 4 \pm 0 \cdot 1$, $c = 5 \cdot 1 \pm 0 \cdot 1$ Å. A pair of strongly interacting dipoles is connected with → (in a different (00*k*) plane with respect to the other pair connected with - - -→)

embrions in new nuclei is possible and the crystallization will advance only by further growth of the confining crystallites. If the segment number is high enough, the variation in the Gibbs thermodynamic potential of n chain-segments changing to crystalline form, $\Delta G = Au^{2/3} + Bn$, may have the surface contribution $An^{2/3}$ smaller than Bn. In this case, a nucleus may be formed, and it also will grow after ultrasonic radiation stops and with quenching below T_g, when the relaxation in the neighbouring binding crystallites is extremely low.

Interesting information on this point has been obtained[4] by measurements based on X-ray analysis. I assume that polyvinyl chloride crystallizes in the orthorhombic system *Pacm* as has been shown by Natta and Corradini[10], according to the scheme shown in Fig. 3.

From the integral line-breadth of the observed reflexions, the mean width of the crystallite $\overline{D}_{200}$, in the direction normal to the (200) plane, increases with radiation time t. On the contrary, the mean width $\overline{D}_{110}$ decreases with radiation even if some recovery may be observed for high values of the radiation time. These results, with the increase in crystalline material, indicated in Fig. 1, suggest the conclusion that, under ultrasonic action, the polymer crystallizes both with formation of new crystallites and growth of those already present. The evidence that crystallization takes place preferentially in the direction normal to the (200) plane (along the a-axis), as I have often observed, is very important, in order to understand what kind of intermolecular force is the most influential in this process. One may explain the existence of this preferred direction by considering the strong forces between carbon–chlorine dipoles of neighbouring chains. In fact, the preferential growth of crystallites along the a-axis offers the possibility of packing the greatest number of dipoles with electric moment orientation of smallest potential energy, the opposite poles of two neighbouring chains being at the shortest distances in the assumed crystalline structure.

Considering that $\overline{D}_{110}$ is always smaller than $\overline{D}_{200}$ ($\sim$ 50 Å. and $\sim$ 60 Å. respectively) in the oriented or isotropic fibre states as obtained by stretching and shrinkage, this indicates clearly that in polyvinyl chloride crystallization the C—Cl dipole–dipole interaction is prevailing over the other Van der Waals's forces.

I thank Dr. M. Mammi, of Centro di Strutturistica Chimica del C.N.R., University of Padua, for essential help given in the analysis of the X-ray patterns carried out in that Institute and for many discussions. Thanks are due also to Dr. F. Smeraldi, technical director of Montecatini-Polymer, who has kindly furnished the polyvinyl chloride fibre prepared under known and reproducible conditions.

INTERACTION OF LIPIDS AND TRYPSIN IN DIMETHYL SULPHOXIDE-WATER SYSTEMS

By Prof. A. LUKTON, H. DONOHUE and Prof. F. A. BETTELHEIM

Chemistry Department, Adelphi College, Garden City, New York

THE nature of the binding sites and binding forces between lipids and proteins is virtually unknown. The attempts that have been made to create model systems for the investigation of this binding have been hampered by solubility limitations. All the systems examined were heterogeneous and included: lipid colloidally dispersed in aqueous protein solution in the presence[1,2] or absence of dispersing agents[1,3], and lipid adsorbed on an inert solid surface and suspended in an aqueous protein solution[4]. The recent use of various non-aqueous lipid solvents in solvating proteins such as dimethyl sulphoxide

(DMS) and formamide[5], affords an opportunity of analysing lipid–protein complexing in a homogeneous system.

We have chosen trypsin for this work. It is particularly suitable because it has a relatively high solubility in water and in DMS and can be transferred from DMS to water with practically no loss in activity[5]. This transfer is necessary because the trypsin esterase activity can be determined only in aqueous medium. Preliminary efforts to demonstrate lipid–protein binding in DMS by observing changes in absorption spectra were unsuccessful. Other attempts to demonstrate strong lipid–protein interaction in DMS also failed. These included a continuous dialysis of lipid–protein DMS mixture against DMS and extraction of the mixture with petroleum ether. In each of these cases the lipid was removed easily. The only indication of an interaction between protein and lipid in DMS was the apparent decrease in enzyme activity.

Four different experiments were performed in observing the inhibition of enzyme activity by lipids:

(*a*) Enzyme and lipids were mixed simultaneously as follows: 3 mgm. of crystalline enzyme (Worthington) were dissolved overnight in 10 ml. of freshly distilled DMS. An 0·5 ml. aliquot of this solution was mixed with 0·5 ml. of a DMS solution of a lipid in concentrations varying from 0 to 4×10^{-3} *M* in DMS. The lipid–enzyme mixture was then added with stirring to 50 ml. of 0·02 *M tris* buffer at *p*H 7·90 which was 0·01 *M* in calcium chloride and 0·04 *M* in sodium chloride. Trypsin esterase activity was then determined by the usual procedure using benzoyl arginine ethyl ester as substrate.

The lipids used were stearic acid and a variety of carotenoids which were kindly supplied by Hoffman–La Roche, Nutley, New Jersey. The carotenoids were chosen to provide functional groups of differing polarity and because of their colour to make observations easier. Included were beta-apo-8′-carotenal *trans*-bixin, *cis-nor*bixin and vitamin *A*.

(*b*) A filtration experiment was performed as follows: Solutions were prepared and mixed as in (*a*). Before trypsin esterase activity was determined, however, the solution was filtered through a fine-pore (5μ) sintered-glass filter. All the colour was removed by this procedure.

(*c*) Mixing afterwards of lipid and enzyme: Solutions were prepared as in (*a*) except that the trypsin in DMS was added to the buffer solution followed by the addition of lipid in DMS.

(*d*) Later mixing of enzyme and colloidal carotenoid: Trypsin dissolved in DMS plus an equal volume of solvent were added to the buffer solution. This was followed by the addition of an aqueous colloidal solution of carotenoid which was prepared by introducing an acetone solution of the carotenoid into buffer and then evaporating the acetone *in vacuo*. The same final concentrations of carotenoid as in (*a*) and (*c*) were used.

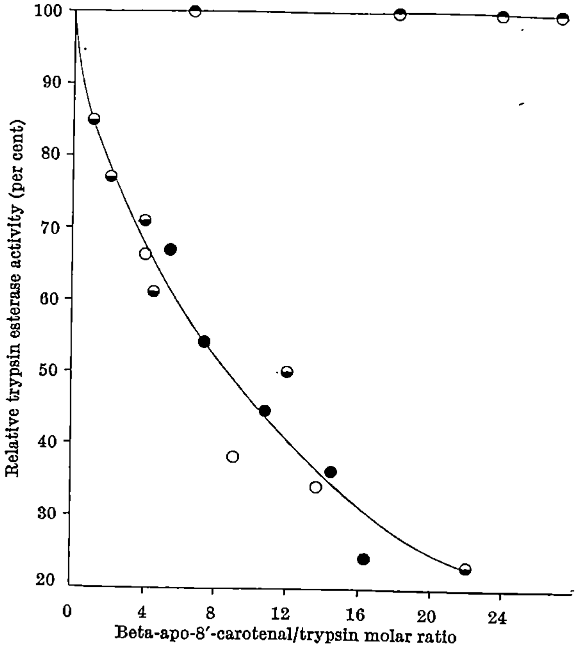

Fig. 1. Trypsin esterase activities at different beta-apo-8′-carotenal to trypsin molar ratios; ◓, subsequent addition of beta-apo-8′-carotenal in DMS to trypsin in DMS dispersed in buffer; ◒, simultaneous addition of beta-apo-8′-carotenal and trypsin in DMS to the buffer, first experiment; ○, same, second experiment; ●, simultaneous addition of beta-apo-8′-carotenal and trypsin in DMS to buffer and subsequent filtration

The results are summarized in Fig. 1 and in Table 1. Among the carotenoids examined the greatest inhibition was observed with beta-apo-8′-carotenal. In Fig. 1, one can see an increase in inhibition with increasing lipid to protein molar ratio which follows a logarithmic course. This occurs only when the lipid and enzyme are premixed in the solvent and, therefore, added together to the buffer. On the other hand, on additions afterwards of lipid in the solvent or the addition of lipid in colloidal aqueous suspension to the buffer into which trypsin in the solvent had been transferred before, there was no apparent reduction in activity. It is evident from the experiment in which the solutions were filtered after addition at the same time of lipid and enzyme to the buffer, that the filtrate showed approximately the same activity as that of the unfiltered material. Therefore, this indicates that the decrease in activity was the result of an aggregated lipid–protein complex of larger than colloidal size, making the enzyme unavailable for reaction. This was confirmed by experiments in which the precipitated complex was isolated in larger quantities. Only a small quantity (about 10 per cent) of the original activity was found in these complexes. At high lipid enzyme molar ratios, the activity determination became more erratic because of the fact that large amounts of enzyme were removed resulting in less accuracy. Other lipids inhibit trypsin esterase activity in a manner similar to that of beta-apo-8′-carotenal. In Table 1, the lipid to enzyme molar ratios required to reduce the enzyme activity to one-half of that in the absence of lipids are given. One can see a direct relationship between the extent of inhibition and the polarity of the lipid molecule[6].

Because of the relationship noted between the polarity of the lipid and extent of enzyme inhibition, activities were determined at various ionic strengths. Solutions of the buffer at *p*H 7·90 were prepared by varying the sodium chloride concentration to give values of ionic strength ranging from 0·065 to 0·50. Three different concentrations of beta-apo-8′-carotenal representing low, intermediate and high

Table 1. MOLAR RATIO OF LIPID TO PROTEIN AT 50 PER CENT RESIDUAL ESTERASE ACTIVITY

Lipid	Functional groups	Molar ratio
Beta-apo-8′carotenal	−CHO	8·3
Trans-bixin	−COOH, −COOCH,	11·8
Stearic acid	−COOH	15·0
*Cis-nor*bixin	−COOH, −COOH	20·0
Vitamin *A*	−OH	66·7

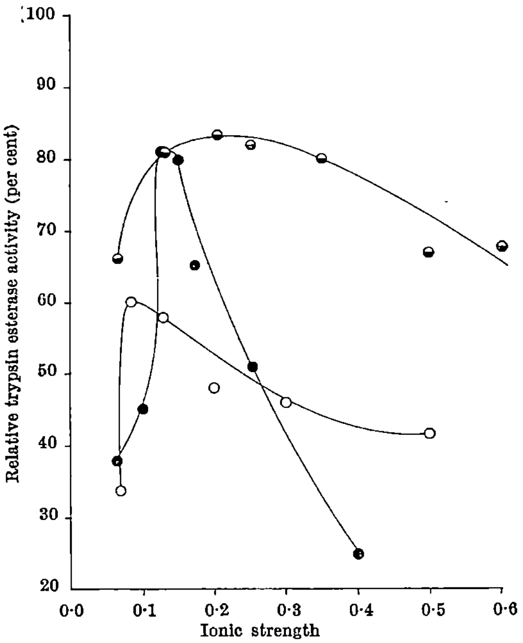

Fig. 2. Relative trypsin esterase activity at different ionic strengths and at different beta-apo-8′-carotenal to trypsin molar ratios; ◒, molar ratio 4 : 1; ●, molar ratio 9 : 1; ○, molar ratio 13·5 : 1

inhibition effects (beta-apo-8′-carotenal/trypsin molar ratio of 4 : 1, 9 : 1, 13·5 : 1) were examined in solutions of various ionic strengths. Trypsin esterase activity was determined as in 1(*a*).

The results are shown in Fig. 2. One can see two main features of the graphs: (*a*) the curves show maxima which appear at lower ionic strengths the higher the beta-apo-8′-carotenal/trypsin molar ratio; (*b*) the activities at an ionic strength of 0·065 followed the results of previous observations, that is, the activities decreased in a logarithmic fashion with the increasing beta-apo-8′-carotenal to trypsin molar ratio. A corollary to this is that the activity values at the maxima of the curves show the same trend.

This indicates that the interaction between protein and lipid is between the polar groups of the molecules or of the aggregate surfaces. At every molar ratio tried, a maximum appears in the ionic strengths of the medium versus activity curve. One may interpret this as two processes competing with each other. The first process which caused a rise in the relative activity with increasing ionic strength can be understood as the depression of interaction between the ionized surface of protein and the polar groups of lipid. One may interpret the second process, in which the activity decreased with increasing ionic strength, as the progressive aggregation of colloidal particles, that is, at high enough ionic strengths the depression of the charges on the protein surface not only decreased the interaction between the lipid and protein, but it also may have decreased the electrical double layer around the colloidal particle, thus enhancing aggregation.

The maxima in the activity curves, therefore, indicate the ionic strengths at which the second process starts to dominate the first. The fact that an inverse relation existed between the lipid to protein ratio and the ionic strength at which the maxima occurred supports this hypothesis.

It would appear that the decrease in enzyme activity was due chiefly to the aggregation of the lipid–protein complexes to larger than colloidal sizes.

We thank Dr. S. Vratsanos for many helpful discussions. This research was partly supported by a grant (*C*–3984 *BBC*) of the National Cancer Institute, U.S. Public Health Service.

RIGIDITY FACTOR OF GELATIN GELS

By Dr. AUDREY TODD
British Gelatine and Glue Research Association, 2a Dalmeny Avenue, London, N.7

PREVIOUS work[1-3] on gelatin fractions has disclosed an unidentified structural feature, termed the 'rigidity factor', which affects the rigidity of gelatin gels. Thus, it has been shown that variations between the rigidities of gels, set and matured either at 0° C. or 10° C., from different gelatin samples are related neither to differences in their molecular weights[2,3] (above a limiting viscosity number[4] $[\eta]$ in molar sodium chloride at *p*H 7 of about 40; that is, $\bar{M}_{\mu} \sim 115{,}000$ (ref. 5)) nor to possible differences in the average number of component chains per molecule[6]. Moreover, the considerable variation in gel rigidity (at high molecular weights) which can occur for gelatins derived by successive extraction from the same pretreated collagen is not accompanied by any apparent change in amino-acid composition[7]. The rigidity factor is reduced during thermal degradation in neutral or alkaline solutions[3]; but it is virtually unaffected by degradation in acid solution[3] or with enzymes or ultrasonics[8]. The present investigation was designed to discover whether the rigidity factor is related to the chain configuration, which would be reflected in the optical rotation of the gel.

Three gelatin samples of widely varying rigidity factor, but of the same high molecular weight and similar in chemical composition, were chosen for this investigation. Two of them (Nos. 76 and 127) were good-quality commercial lime-processed ox-hide gelatins; and the third (*AT*/1*a*), of very high rigidity, was prepared in the laboratory, as a neutral first extract from demineralized ossein (from the mixed bones of Indian cattle), by adaption of the accelerated alkaline pretreatment process of Ward[9]. The three gelatin samples would not differ significantly in amino-acid composition, since they were all derived from the same species of mammal[10]; and they would exhibit the low isoionic point $pI \sim 5$ typical of gelatins prepared by an alkaline process[11], corresponding to the conversion of most of the amide groups of the glutamine and asparagine residues of collagen to carboxyl groups[12].

Optical rotation and rigidity measurements were carried out on gels, from these three samples, which had been prepared under identical conditions and carried through exactly the same schedule of changes in temperature. Each gelatin sol, containing 5·5 gm. protein/100 ml. at pH 7, was filtered through a No. 3 sintered-glass funnel and used to fill either a 1-dm. jacketed polarimeter tube or a type A rigidity tube[13] at 40° C., and then quenched rapidly to 0° C. and left to mature overnight. Readings were taken at 10-min. intervals over a period of 23 hr. 15 min.–24 hr. 45 min. at 0° C., so that the mean of the 10 readings corresponded to 24 hr. maturing at 0° C. The temperature was then raised as quickly as possible (during 30 min.) in 10 deg. C. stages, taking care never to exceed the required temperature. Readings were taken at each temperature, particularly (10-min. intervals) over the 1½-hr. period corresponding to a mean of 3 hr. at 10, 20 and 30° C., and to 65 min. at 40° C. It was found in all cases that, over these 1½-hr. periods of measurement from 0 to 30° C., the optical rotation, as well as the rigidity[8], was changing very slowly and (within experimental error) linearly with time, so that the means of these observations were adequate for comparative purposes. At 40° C. there was no detectable change in optical rotation over the period of measurement. All temperatures were controlled to within ± 0·1 deg. C.

The optical rotation measurements were made for the sodium D line using a Bellingham and Stanley model A visual polarimeter with a screened light source in a dark-room at a half-shade angle of 8°. The glass scales were illuminated weakly by 2·5-V. torch bulbs set behind ¼-in. green 'Perspex', so that the dark adaptation of the eye was not destroyed between successive measurements. Zero readings were obtained by washing and refilling the polarimeter tube with distilled water (via the thermometer side-arm), without disturbing the end-plates, and repeating the measurements at each temperature. Following the suggestion of Bates *et al.*[14], condensation on the end-plates at temperatures below the dew-point was avoided by the addition of 'Perspex' chambers, containing silica gel and closed by a second pair of glass windows, to the ends of the polarimeter tube. To facilitate rigidity measurements on the weaker gels, carbon tetrachloride coloured with a small amount of a solid dye, 'Waxoline Red *O.S.*', was used instead of mercury[13] as the capillary fluid, and a dual system of manometers, one containing mercury and the other carbon tetrachloride, was employed to obtain and to record the required wide range of applied pressures. Protein concentrations at 40° C. were determined in duplicate by evaporating 20-ml. portions of the excess gelatin sol to constant weight in an oven at 105° C.; the residues were then corrected for the weights of inorganic material present by moistening them with concentrated sulphuric acid, charring them over a low flame, and igniting them in an oven at 550° C. for 2 hr.

The optical rotation measurements are shown in Table 1 and Fig. 1. From the results for duplicate runs on gelatin 127, the coefficient of variation of the specific rotation $[\alpha]_D$ is less than 1 per cent from 0 to 30° C. and only about 0·15 per cent at 40° C. Therefore, the differences between the specific rotations of the three gelatins are significant at each temperature. Sample 76/2/1 was a 50 per cent top fraction of an 87 per cent middle fraction obtained from gelatin 76 by coacervation with ethanol[15]. The specific rotation results for 76/2/1 are not significantly different, at any temperature, from those of the original gelatin 76 indicating that, at least for material of relatively high average molecular weight, the differences in molecular weight distribution are unimportant.

Table 1. SPECIFIC ROTATION OF GELATIN GELS AND SOLS

Gelatin No	76	76/2/1	127		*AT*/1*a*
$[\eta]$ in M NaCl, pH 7, 40° C.	61	63	64		62
Conc. gm. protein/100 ml.	5·591	5·452	5·461	5·504	5·365
pH	6·85	7·88	6·94	6·89	6·98
$-[\alpha]_D$ at 0° C.	301·9	306·5	329·3	326·9	334·1
10° C.	269·9	269·1	302·8	304·2	315·3
20° C.	208·7	212·0	257·3	255·9	264·8
30° C.	150·1	148·6	163·0	161·0	174·7
40° C.	141·3	141·4	144·2	143·9	144·6

The corresponding rigidity measurements for the three gelatins are given in Table 2. A slight increase of the apparent rigidity modulus G (that is, shear stress/shear strain) with strain was observed for some of the gels, and so measurements for all the gels were made at the same small maximum strain (at the tube wall) of 0·15 (or interpolated graphically to this value). Thus, although the values of G recorded in Table 2 are not true rigidity moduli, they should be close enough to the constant theoretical elastic moduli for comparative purposes[13].

When the specific rotations in Table 1 were plotted against the apparent rigidity moduli in Table 2, for the same gels after exactly the same treatment, the points lay on a single smooth curve, showing that $[\alpha]_D$ and G are closely related. In Fig. 2, a linear correlation is seen to exist between $-[\alpha]_D$ and $G^{\frac{1}{2}}$, where the values of G in Table 2 have been corrected

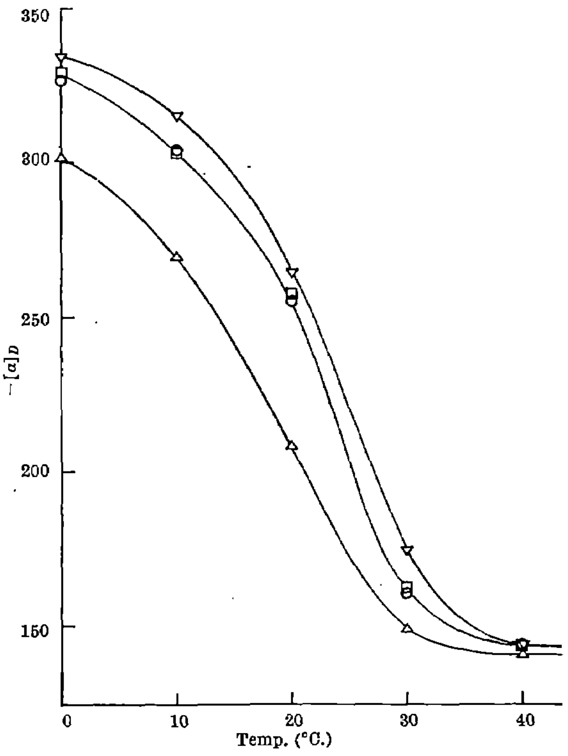

Fig. 1. Variation of specific rotation of three samples of gelatin: ▽, *AT*/1*a*; □, 127 run 1; ○, 127 run 2; △, 76

Table 2. Rigidity of Gelatin Gels

Gelatin No.	76	127		*AT*/1*a*
Conc. gm. protein/100 ml.	5·416	5·499	5·488	5·160
*p*H	6·95	6·96	6·97	6·98
G dynes/cm.^{2} at 0° C.	71,070	108,380	108,580	119,960
10° C.	45,910	72,230	72,180	80,370
20° C.	12,360	36,310	35,040	43,340
30° C.	~ 6	~ 19	~ 14	188

to a concentration C of 5·50 gm. protein/100 ml. (taking $G \propto C^2$, over at least a small range of C, from the work of Ferry[16] and Ferry and Eldridge[17]).

The conditions of these experiments (that is, gelatins of similar chemical composition at the same concentration and *p*H) were chosen so that the contributions to the optical rotation from the individual amino-acid residues and from environmental factors were as nearly constant as possible at each temperature. The fairly close values of the specific rotation for sols of the three gelatins at 40° C. (Fig. 1), where the molecules are present as random coils[18], is good evidence that this constancy was virtually attained. Hence, the increase in magnitude of the specific rotation for the gels must be, essentially, a measure of the amount of regular structure or chain folding in the gel phase (providing that only one type of folding is present, and that there is no appreciable variation in environmental contributions as the temperature falls). Thus, it follows from the correlation in Fig. 2, that the rigidity modulus of a gelatin gel, for a given concentration, is also determined by the amount of chain folding, and the 'rigidity factor' defines the capacity of a gelatin molecule to fold in a regular manner.

There is substantial evidence, from X-ray diffraction work[19] and from the similarity of the melting temperatures for mixtures of collagen or gelatin with ethylene glycol[20], that this regular folding in gelatin gels is the same type of triple helix present in native collagen[21]. The unusual negative chain-configurational contributions to the specific rotation given both by gelatin gels[22,23] and by soluble collagens[23] are also consistent with this view. An isotropic gelatin gel must, therefore, contain lengths of randomly orientated triple helix (formed from portions of three gelatin molecules), which bind the molecules into a network and confer stiffness on the structure. There appears, at present, to be no theoretical model for this type of structure. Qualitatively, however, its mechanical behaviour would be expected to resemble that of a frozen unstrained rubber inasmuch as the modulus of the unorientated crystallites (or helices in the gel) would be superimposed on that of the amorphous network[24]. It is not yet known whether a higher rigidity factor corresponds to more, or to longer, triple helices.

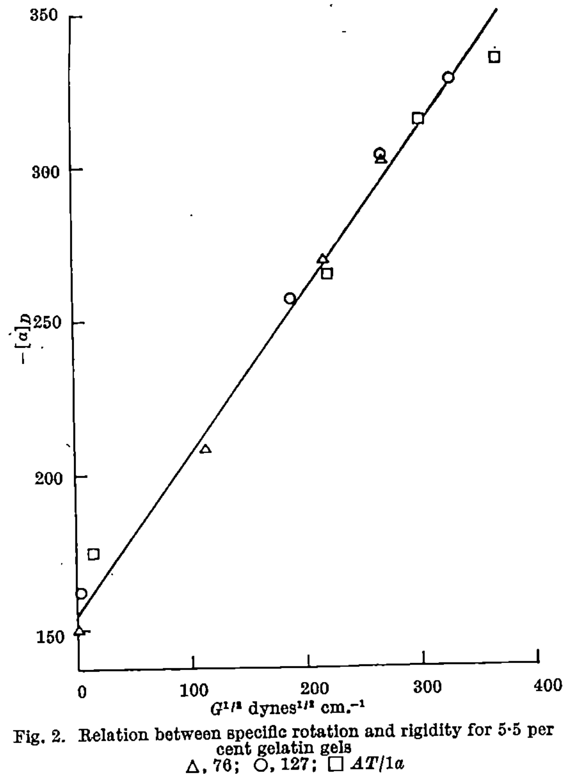

Fig. 2. Relation between specific rotation and rigidity for 5·5 per cent gelatin gels
△, 76; ○, 127; □ *AT*/1*a*

Although it has been established that the rigidity factor of a gelatin gel measures the facility of the molecules to take part in reforming the collagen triple helix, the precise nature of the structural feature which is responsible remains obscure. Further evidence that the molecular structure of the three gelatin samples is not completely identical is shown by the small but significant differences between the specific rotations of the sols at 40° C. in the absence of chain order. It is possible that this small variation in the contributions to the specific rotation from the individual residues is due to subtle differences in amino-acid composition which are not detectable by the present experimental techniques. A more likely explanation, however, is that differences in the mutual interactions of the individual residues are produced by changes of amino-acid sequence along the gelatin chains: the rigidity factor would then be determined by the proportion of residues in sequences capable of forming the collagen fold.

TEICHOIC ACIDS AND THE STRUCTURE OF BACTERIAL WALLS

By Dr. A. R. ARCHIBALD, J. J. ARMSTRONG, Prof. J. BADDILEY, F.R.S., and J. B. HAY

Department of Chemistry, King's College (University of Durham), Newcastle upon Tyne

THE chemical composition of the walls of a number of bacteria has been examined by many workers[1,2] and much interest has been expressed in the possible function of the various components. Electron microscopy of stained sections of whole cells of *Bacillus subtilis* has shown that the wall of this organism appears to be composed of three layers (for example, ref. 3), although the interpretation of such micrographs may be ambiguous. We have now examined stained sections of the isolated walls of *Lactobacillus arabinosus*, *L. casei*, *L. fermentii*, *B. subtilis* and *B. cereus*, and observed three layers in each case.

Vigorous extraction of lyophilized walls of *L. arabinosus* completely removes the teichoic acid and a polysaccharide containing rhamnose, galactose and glucosamine[4]. After such extraction, the insoluble residue (50 per cent of the original weight of wall) consisted of the mucopeptide component, which is composed of alanine, glutamic acid, diaminopimelic acid, glucosamine and muramic acid; all the glucose, rhamnose, galactose and teichoic acid which were originally present in the wall had been removed. This mucopeptide material contained about 0·4 per cent of phosphorus, which was not present as teichoic acid[4]. The nature of the phosphorus is unknown, but it is of interest that after complete removal of teichoic acid from the walls of *Staphylococcus aureus* a similar quantity of phosphorus remained[5]. Furthermore, some twelve species of Gram-positive bacteria containing no teichoic acid in their walls nevertheless contained small amounts of phosphorus (0·2–0·6 per cent) chemically bound in the wall.

Electron microscopical examination of shadowed specimens of the mucopeptide from *L. arabinosus* showed that it retained the shape of the original cell wall, indicating that in these walls the mucopeptide is the component responsible for the structural integrity of the wall, the teichoic acid and polysaccharide being of minor importance in this respect. Similar results were obtained on extracted walls from *B. subtilis* which contained only traces of teichoic acid. This finding is similar to that of Park and Hancock[6], who showed that the residual material obtained after exhaustive extraction and enzymic digestion of whole cells of *Staph. aureus* had the composition of a mucopeptide and the appearance of cell walls. Moreover, we have observed that stained sections of extracted walls of *L. arabinosus* possess a three-layer structure similar to that of the original walls. This suggests that the mucopeptide is not homogeneous, a finding which is in accord with views expressed by others[7,8] on the basis of chemical investigations. The appearance of walls before and after removal of teichoic acid is shown in Fig. 1.

In view of modern opinion that walls are not solely rigid supports for the cell, it is interesting to consider possible functions of wall teichoic acids. As they do not contribute significantly to the rigidity of the wall, it is possible that they are concerned in cell metabolism. After isolation, they have charged phospho-mono- and di-ester groups and also free amino-groups[9,10]. Thus it might be expected that the provision of charged groups is one of the functions of teichoic acids. Consequently, it was necessary to investigate the manner in which teichoic acid is bound to the cell wall, and to determine whether the charged groups of teichoic acid exist as such in the wall structure.

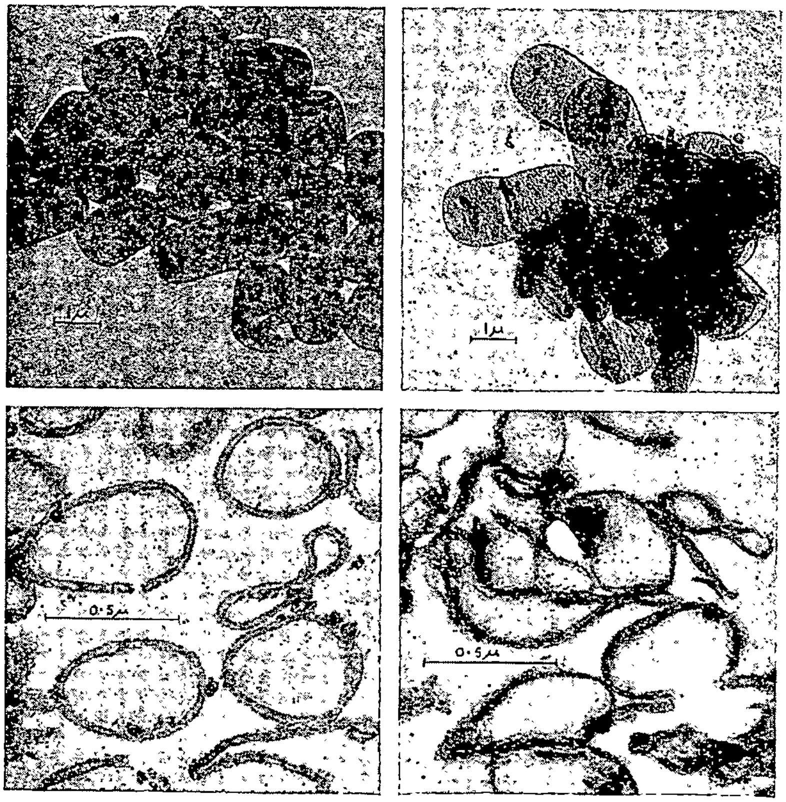

Fig. 1. Top left, walls of *L. arabinosus*; top right, walls of *L. arabinosus* after removal of teichoic acid and soluble polysaccharide; bottom left, section of walls of *L. arabinosus* stained with permanganate; bottom right, section of walls of *L. arabinosus* after removal of teichoic acid and soluble polysaccharide

It is unlikely that teichoic acids are bound to the walls by amide linkages involving the amino-groups of the D-alanine residues. These residues are joined to the teichoic acid molecule through exceptionally labile ester linkages which are nevertheless largely unaffected by the acid extraction procedures. It is improbable that amides would be hydrolysed under conditions which do not hydrolyse these ester linkages. Extraction of teichoic acid was effected more readily by trichloroacetic acid than by any of the other treatments described (Table 1). However, the amount of alanine released was greater in alkaline than in acidic or neutral solution, and the molar ratio of alanine liberated : teichoic acid phosphorus liberated was very much higher in alkaline than in acidic solution. For example, 2 *N* ammonia at room temperature released the alanine from walls, partly as alanine amide, without simultaneous release of comparable amounts of teichoic acid. Alanine and its amide were formed similarly from the walls of *Staph. aureus* (Oxford), *albus, citreus* and *Streptococcus faecalis*. It follows that teichoic acid is not bound to the wall by covalent linkages involving the amino-groups of the O-alanyl ester residues.

Table 1. EXTRACTION OF TEICHOIC ACID AND ALANINE FROM ISOLATED WALLS

Results are expressed as moles/mole of phosphorus originally present in the wall

	Reagent	Phosphorus in solution	Alanine in solution	Ratio alanine: phosphorus
L. arabinosus	5 per cent trichloroacetic acid, 24 hr., 28°	0·71	0·36	0·51
,,	0·1 *M* acetate, *p*H 6·5 24 hr., 28°	0·102	0·40	3·95
,,	0·1 *M* acetate, *p*H 9, 24 hr., 28°	0·15	0·61	4·0
,,	2 *M* ammonia, 3 hr., 18°	0·038	0·37	9·7
,, (pretreated with ammonia)	5 per cent trichloroacetic acid, 24 hr., 28°	0·44	0·02	0·05
B. subtilis	5 per cent trichloroacetic acid, 24 hr., 28°	0·88	0·36	0·41
,,	Water, 3 hr., 18°	0·023	0·02	0·91
,,	2 *M* ammonia, 3 hr., 18°	0·039	0·29	7·4
Staph. aureus (Duncan)	5 per cent trichloroacetic acid, 24 hr., 28°	0·67	0·55	0·82
,,	Water, 3 hr., 18°	0·059	0·055	0·93
,,	2 *M* ammonia, 3 hr., 18°	0·121	0·60	5·0

This conclusion has been confirmed for *L. arabinosus, B. subtilis* and *Staph. aureus* (Duncan) by treatment of their walls with fluorodinitrobenzene. The results are shown in Table 2. The reaction is heterogeneous in these experiments and thus is not necessarily complete, particularly as the walls studied may differ in their permeability towards the reagent. It is noteworthy that since reaction is usually effected at *p*H 7·8 or even *p*H 9 for several hours, a considerable proportion of alanyl ester groups would be expected to hydrolyse, liberating alanine or dinitrophenylalanine into solution. This was observed in the cases examined here. Thus, in the examination of terminal groups in bacterial cell walls which contain labile amino-acid residues, it is essential to examine the supernatant solution as well as the dinitrophenyl-walls, a procedure which, in the past, has not been followed[11].

Table 2. DINITROPHENYLALANINE FORMED ON TREATMENT OF WALLS WITH FLUORODINITROBENZENE

Conditions used were similar to those described by Salton (ref. 11). Results are expressed as moles dinitrophenylalanine/mole phosphorus originally present in walls

	Wall hydrolysate	Supernatant and water washings	Total
L. arabinosus	0·35	0·17	0·52
B. subtilis	0·17	0·11	0·28
Staph. aureus	0·32	0·18	0·50

The ribitol teichoic acids examined in detail (from *B. subtilis*[10] and *Staph. aureus*[5]) are polymers in which glycosylribitol units are joined together in a regular manner through phosphodiester groups at the 1- and 5-positions in the ribitol. Moreover, each polymer contains only one phosphomonoester group, which is situated exclusively at the 5- position of a terminal glycosylribitol unit. This has also been observed in the teichoic acid from *L. arabinosus* (unpublished observation). It follows that these compounds cannot be attached to the bacterial wall through phosphotriester linkages, as the fission of such linkages would result in the appearance of some 2,5-phosphodiester linkages or of some terminal phosphomonoester groups at positions 1 and 2 in the ribitol. Some polymer lacking a terminal phosphomonoester group would also be expected. These consequences are apparent from work in the nucleotide field[12]. Phosphotriester linkages of the type required would be extremely labile towards alkali, and this is inconsistent with the observed rate of liberation of teichoic acids from walls under alkaline conditions.

Thus, in the native walls the teichoic acid has free phosphate and amino-groups, and is presumably held in the wall through ionic linkages and hydrogen bonds. This would result in the walls bearing a charge, a conclusion supported by several observations. The ease of centrifugation of walls under various conditions can be explained on this basis, native walls being much more readily sedimented from dilute salt or trichloroacetic acid than from water. The ease of sedimentation of extracted walls in water is much greater than that of unextracted walls, and is not appreciably different from that of suspensions in dilute salt solutions. Moreover, in electron microscopical examination of natural and extracted walls we have observed repeatedly that, whereas in shadowed specimens and in stained sections native walls are well dispersed, extracted walls show a marked tendency to aggregate. These properties could arise through mutual electrostatic repulsion of the unextracted walls, this repulsive force being reduced after removal of the teichoic acid.

The ionic nature of teichoic acids in walls is consistent with the view that these compounds may regulate the passage of ions between the organism and its environment. It is perhaps significant that *Lactobacilli*, many of which contain teichoic acids in their walls, can grow in acid solutions and in the presence of fairly high (4 per cent) salt concentrations; similarly. *Staph. aureus, albus* and *citreus* grow in 10 per cent sodium chloride, *B. subtilis* in 7–12 per cent and *Strep. faecalis* in 6·5 per cent sodium chloride.

We acknowledge the award of a Frank Schon fellowship (to A. R. A.) and a Salters fellowship (to J. J. A.). We also thank Mr. A. L. Davison for the growth of bacteria, Mr. E. H. Boult and Miss B. Harris for electron microscopy, and the Medical Research Council and Nuffield Foundation for financial support. Walls of *Staph. aureus* (Duncan) were kindly provided by Dr. P. Mitchell.

MECHANISM OF ACTION OF ANTIGEN-ANTIBODY COMPLEXES: THEIR EFFECT ON MAST CELLS

By Dr. IVAN MOTA

Department of Histology, University of São Paulo

RECENTLY, Germuth and McKinnon[1] have made the important observation that soluble antigen-antibody complexes prepared in excess antigen produce anaphylactic shock when injected into unsensitized guinea pigs. A syndrome similar to anaphylaxis was also obtained by injection of soluble complexes in mice by Tokuda and Weiser[2] and in rats by Arocha and McIlreath[3]. The observation that in the above-mentioned animals the character of the shock induced by soluble antigen-antibody complexes was very similar to that seen in anaphylaxis has suggested that the sites of antigen-antibody action are the same regardless of whether anaphylaxis is induced by injection of antigen into an already-sensitized animal or by injection of soluble preformed antigen-antibody complexes. It is known that mast cell damage and histamine release occur in guinea pig active or passive anaphylaxis[4–6], as well as in rat and mouse active anaphylaxis[7–10], so I thought it would be interesting to find out whether soluble antigen-antibody complexes would duplicate damage to mast cells and release of histamine observed in anaphylaxis.

Crystalline bovine serum albumin was used as antigen. The antiserum was a pool of rabbit anti-bovine serum albumin containing 1·0 mgm. antibody nitrogen/ml.

To prepare the soluble complexes antigen was added to antiserum at equivalence, the mixture incubated at 37° C. for ½ hr. and kept for 24 hr. at 4° C. The precipitate was then washed three times with saline at 0–1° C., re-suspended in Tyrode solution containing a total amount of bovine serum albumin ranging from 5 to 8 times that used to precipitate antibody at equivalence, stored at 4° C. with occasional agitation for 48 hr. and cleared by centrifugation.

Twenty guinea pigs each weighing 250 gm. were injected intravenously with 2 ml. (2 mgm. antibody nitrogen) of the complexes preparation. Three of these guinea pigs died with emphysematous lungs, 10 presented severe shock and died overnight, 2 presented slight to moderate shock and 5 presented no effect. The emphysematous lungs were then fixed and stained for microscopical observation of the mast cells as described elsewhere[4]. However, a microscopical inspection of many fields did not reveal any mast cell degranulation. Nevertheless, it was considered that the amount of histamine released, although enough to induce emphysema, was insufficient to produce any visible mast cell damage and it was decided to perform *in vitro* experiments, in which the effect of the complexes on the mast cells could be detected more easily. Thus, 15 guinea pigs were killed by breaking the neck, their lungs, ileum and mesentery dissected out, and the activity of the complexes tried on these organs. The ileum was suspended in a Dale apparatus with 7 ml. capacity and the activity of preparations of the complexes tested by adding 0·4 ml. (400 μgm. antibody nitrogen) of them to the bath. The lung was cut in slices 0·8 mm. thick, washed in cold Tyrode solution, and 10–12 of these slices used as samples. They were then shaken in beakers closed with 'Parafilm' caps for 15 min. at 37° C. in 4 ml. (4 mgm. antibody nitrogen) of preparations of the complexes or in 4 ml. of Tyrode solution, after which the histamine content of the supernatants was assayed on the guinea pig ileum. The mesentery was cut into pieces which were incubated with the complexes under the conditions described for the lung, and then transferred to a 4 per cent solution of lead subacetate for fixation[4].

Six of the 15 ilea tested responded to the complexes with a definite contraction followed by desensitization as already reported[11]. However, no release of histamine or damage to mast cells could be detected when the lungs or mesentery of the same animals were incubated with the complexes. The same results were obtained when 1 per cent fresh guinea pig serum was added to the complexes. Twenty rats were injected intravenously with 2 ml. (2 mgm. antibody nitrogen) of the preparation of complexes. All the animals presented moderate to severe shock, but there were no fatalities. It was then observed that adrenalectomized rats were very susceptible to the effect of soluble antigen-antibody complexes and 15 rats adrenalectomized 48 hr. before were injected intravenously with 1 ml. (1 mgm. antibody nitrogen) of the complexes. All the animals showed severe shock and 12 died showing generalized intestinal congestion at autopsy. For microscopical observation of the mast cells, the skins of the snout and the tongue were fixed by injecting fixative through the carotid artery as described elsewhere[8]. However, no damage to the mast cells was observed, except for one rat in which there was generalized damage of these cells. This experiment was duplicated with a group of 12 adrenalectomized rats from which blood was collected 5 min. after injection of the complexes and the plasma histamine assayed on the ileum. Although all the animals showed severe shock no increase in plasma histamine was detected, except for one animal in which 0·5 μgm./ml. of histamine was found. Twenty mice were then injected with 0·5 ml. (0·5 mgm. antibody nitrogen) of the complexes. All the animals showed moderate to severe shock, and 9 of them died within 10 min. However, microscopical examination of their tissues did not reveal any damage to the mast cells. Pretreatment with *B. pertussis* aggravates the shock induced by soluble antigen-antibody complexes in mice[2] and 20 *pertussis*-treated mice were injected with 0·5 ml. of soluble complexes. Although 18 of these mice have presented severe shock and died within 20 min. no damage to the mast cells could be observed in their tissues.

These results showing that guinea pigs, rats and mice injected with antigen-antibody complexes in excess antigen present an anaphylactic picture similar to that observed in anaphylaxis confirm the results of several authors[1-3]. However, I have not been able to duplicate by means of soluble antigen-antibody complexes the damage to mast cells and release of histamine observed in anaphylaxis.

I consider these results show that neither release of histamine nor damage to mast cells occurs when guinea pig lung or mesentery is incubated with soluble antigen-antibody complexes, under conditions in which both damage to mast cells and release of histamine are promptly produced when antigen contacts sensitized tissues[5]. Furthermore, my results suggest that the complexes do not act as a histamine releaser or by sensitizing the tissues and reproducing passive anaphylaxis. Also the possibility that anaphylatoxin could have been formed by reaction between antigen-antibody complexes and serum proteins is ruled out as anaphylatoxin induces damage to mast cells similar to that produced by antigen-antibody reaction in anaphylaxis[12]. These results certainly do not exclude that soluble antigen-antibody complexes may be operative in anaphylaxis, but suggest that the complexes are not able, or at least not quite efficient, in duplicating the cytological aspects of anaphylaxis connected with liberation of histamine. However, that this may be possible under certain conditions is suggested by my observation that some of the adrenalectomized rats show damage to mast cells and release of histamine when injected with soluble complexes. This same fact, or a possible difference in the composition of the complexes used, may explain the results of Arocha and McIlreath[3], who have reported release of histamine from the isolated lung of the guinea pig or small intestine of the rat when perfused with soluble antigen-antibody complexes. However, the experiments reported here suggest strongly that soluble antigen-antibody complexes do not preferentially act by releasing histamine from the mast cells.

CHROMATOGRAPHIC ANALYSIS OF INFECTIOUS RIBONUCLEIC ACID FROM POLIOVIRUS

By C. COCITO, A. PRINZIE and P. De SOMER

Rega Institute, Department of Virology, University of Louvain, Belgium

TWO metabolically distinct types of ribonucleic acids (RNA) have been recognized in mammalian and bacterial cells: a low molecular weight or soluble component (LMW-RNA) which is apparently free in the cytoplasm[1] and able to transfer the activated amino-acids to the ribosomes[2], and a highly polymerized form or high molecular weight component (HMW-RNA) linked to a protein moiety in a ribonucleoprotein structure (RNP, ribosomes) which is regarded as the major site of protein synthesis[3]. Another type of RNA is that of the mature particles of some plant and animal viruses (viral RNA), which seems able to direct the synthesis of the whole virus by a suitable host cell. Numerous publications have, in fact, reported the infectivity of naked RNA extracted with cold[4,5] or hot[6] phenol from different viral particles.

The system of cells infected with viral RNA from poliovirus presents a particular difficulty, because once extracted with phenol, most of the protein-free polio-RNA apparently remains no longer infectious[7]: a decrease of 3–5 log units is usually observed in different experiments, an upper limit of 1 per cent residual infectivity being only recently reported[8].

Some experiments of partition chromatography described in the present article were carried out to examine the relationships between cellular and viral RNA's, and to analyse the infectivity of protein-free RNA from poliovirus with a possible exclusion of cellular constituents. Our work is based on the use of a chromatographic column (protein-coated 'Supercel') which can separate the high molecular weight RNA (found by us only in the ribosomes) from the low molecular weight RNA (found mainly, but not only, in the supernatant on centrifugation of bacterial homogenates at 100,000*g*) and from the precursors contained in the phenol extracts of *E. coli*[9,10]. Such a column has also been used for research on deoxyribonucleic acids (DNA) from bacteriophages[9] as well as for the analysis of RNA metabolism in phage-infected bacteria[10] and of HeLa cells infected with different DNA- and RNA-viruses[11], because it allows separation of small amounts of nucleic acids without the necessity for previous isolation from large quantities of contaminating precursors. The column comprises analytical grade cellulose powder, protein-coated 'Supercel', 'Supercel' coated with albumin made basic by methylation and washed with 0·3 *M* buffered sodium chloride, 'Supercel'. Procedure of methylation and details for preparation of the column are to be found in refs. 9–14.

HeLa cells employed throughout this work were cultured in suspension in spinner flasks incubated at 37° C., using as growth medium Hank's solution lacking calcium and magnesium but supplemented with ten times as much phosphorus and with 5 per cent decomplemented calf serum and 0·5 per cent lactalbumin hydrolysate. Medium 199 added with carrier-free preparations of phosphorus-32 labelled orthophosphate to a specific activity of 1 or 2 µc. phosphorus-32/µgm. phosphorus-31 was used to yield radioactive cells. Virus stocks were prepared by infecting monolayers of either HeLa cells or monkey kidney primary cultures with multiplicities 1–5 of poliovirus type *I*, allowing an incubation of 20 hr. at 37° C. When labelled virus had to be obtained, after the contact with the virus, monolayers were washed with a phosphorus-free Hank's solution buffered at *p*H 7·6 with 0·01 *M tris* and then covered with medium 199 added with phosphorus-32 labelled inorganic phosphate. After lysis had occurred, cellular debris was spun down by low-speed centrifugation: spontaneous lysates thus obtained had the usual titre of 1 × 10^7–5 × 10^7 plaque-forming units (pfu)/ml. The virus was concentrated either by centrifugation at 100,000*g* for 2 hr., or by precipitation at *p*H 3·5 and 3° C. with hydrochloric acid and yeast-RNA as carrier: with the first method up to 10^5 pfu/ml. and with the second 10^3 pfu/ml. remained in the supernatant. Virus suspensions of high titre were also obtained by sonicating at 3° C. cells collected by centrifugation 10 hr. after infection with poliovirus, but these preparations were heavily contaminated by cellular RNA's and ribosomes. A further purification of the concentrated virus preparation could be achieved through a treatment with RNase at 37° C. followed by ultracentrifugation in the cold to remove the enzyme. Titrations of viable virus were usually performed on monolayers of trypsin-dispersed monkey kidney cells, following Dulbecco and Vogt's plaque-technique[15].

For the extraction of cellular RNA's, HeLa cells washed free from the radioactivity of the medium and suspended in 0·1 *M* sodium chloride buffered at *p*H 7·1 with 0·1 *M* sodium phosphates were extracted three times with water-saturated redistilled phenol at 60° C. and constant stirring: such procedure, however, proved to be unsuitable for the extraction of poliovirus, since a loss of the whole viral infectivity occurred when temperature exceeded 40° C. during the phenol treatment. For the preparation of viral RNA, concentrated suspensions of virus in the same buffered saline were extracted three times with phenol at 3° C.; residual phenol was removed by five extractions with peroxide-free ether and the latter eliminated by bubbling a stream of sterile nitrogen[10]. Preparations of cellular and viral RNA's were eluted from a protein-coated 'Supercel' column with a linear gradient of sodium chloride 0·3 → 1·5 *M* constantly buffered at *p*H 6·7 with 0·05 *M* phosphates[10]. The adsorption at 254 mµ and radioactivity of the eluate were continuously measured with ultra-violet adsorption and count-rate meters, and simultaneously recorded: measures with ultra-violet optics were omitted when infectivity of viral RNA had to be titrated on monkey kidney monolayers[15]. Molarity of a given fraction was obtained from the formula $C = C. + C_f(e^{x/v} - 1)e^{-x/v}$, where $C.$ = concentration of the mixer; C_f = concentration of the feeder; x = volume delivered less column displacement; v = vol. of the mixing vessel. A step-wise elution was also carried out with solutions 0·3 *M*, 0·5 *M*, 0·7 *M*, 1·0 *M* and 1·5 *M* sodium chloride buffered at *p*H 6·7, in which case the whole infectivity was eluted at 1·0 *M*. The optical density of the single fractions was measured in a Unicam spectrophotometer and the radioactivity with a gas-flow counter.

Fig. 1*b* shows the elution pattern of phosphorus-32 labelled compounds from HeLa cells: similarly to that observed with *E. coli*[10], peak *A* contains free bases, nucleotides and optically inactive phosphorus-32 labelled compounds (precursors), peak *B*, RNA of low molecular weight (LMW-RNA), and peak *D*,

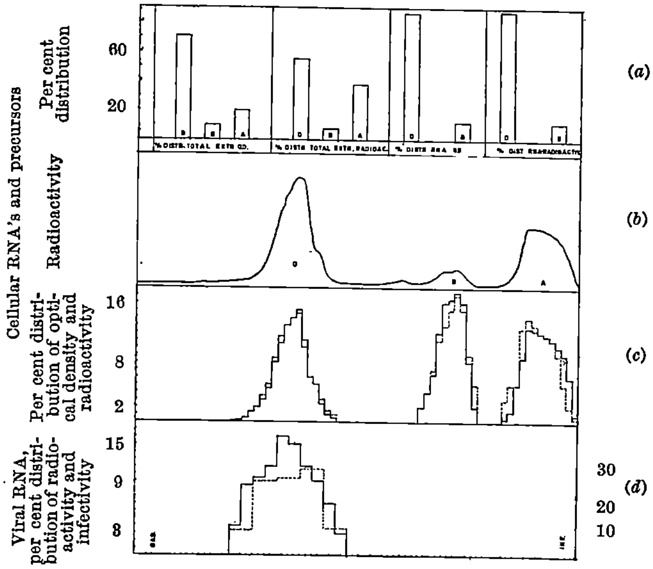

Fig. 1. Chromatographic patterns of cellular RNA's and precursors, and of infectious viral RNA from labelled poliovirus *a*, Per cent distribution of total optical density and radioactivity extracted from the cells among the three chromatographic fractions and similarly for the RNA-radioactivity and ultra-violet adsorption; *b*, elution pattern of phosphorus-32 labelled compounds extracted with phenol from HeLa cells grown for four generations in the presence of phosphorus-32 labelled orthophosphate. Peaks *B* and *D* represent cellular RNA's; precursors are contained in the fraction *A*; *c*, per cent distribution of optical density at 254 mµ (dashed lines) and radioactivity (continuous lines) among the three chromatographic peaks. Total ultra-violet adsorption and radioactivity within each peak considered equal to 100; *d*, per cent distribution of radioactivity (continuous lines) and infectivity (dashed lines) of viral RNA extracted with cold phenol from phosphorus-32 labelled poliovirus prepared on monkey kidney cell monolayers

of high molecular weight (HMW-RNA). The peak C of DNA, which is located between the two RNA-regions, does not appear because of the DNA-exclusion during extraction with hot phenol; it appears, however, when extraction is carried out at a lower temperature, that is, at 4°–40° C., and on addition of detergent, namely, sodium dodecyl sulphate 0·5–4 per cent, in which case the repartition of radioactivity among the three nucleic acid fractions is the following: $B : C : D = 8 : 32 : 60$. Figs. 1a and 1c show the distribution (per cent) of both ultra-violet adsorption and radioactivity among the three chromatographic fractions. Within the same area of (high molecular weight) RNA from the host cell, viral RNA is also eluted, as shown in Fig. 1d, in which the distribution of both radioactivity and infectivity for monkey kidney cell monolayers are reported (practically, 100 per cent of the viral RNA infectivity loaded on the column was recovered within this peak).

These experiments indicate that viral RNA from poliovirus behaves chromatographically in a similar way to cellular HMW-RNA, but quite differently from LMW-RNA. Differences between the two types of cellular RNA's in relation to the method of partition chromatography used have been discussed[9,10]. The recovery of infectious naked RNA from poliovirus by partition chromatography indicates that the protein-coated 'Supercel' column could be a suitable means for purification and isolation of viral RNA. In addition, our results may support further the view that isolated poliovirus-RNA is fully infectious, and exclude the participation of other viral or cellular components in such infectivity, a view that is in agreement with the theory of viral RNA as carrier of genetical information, since protein-free RNA's, but not nucleoproteins, seem to be eluted from our column. We have been unable to find any difference between inactive and infectious viral RNA from poliovirus extracted with phenol, and the reason for the partial inactivation at 0° C., when compared with the complete loss occurring at 60° C.

Note added in proof. While this work was in the press, Dr. L. Philipson (Rockefeller Institute, New York) informed us that with suitable gradients two fractions of high molecular weight RNA having sedimentation coefficients of 16 and 25–29 can be separated further on the type of column we have used, and that the DNA extracted with cold phenol from HeLa cells has an $S^0_{20,w}$ of 38, corresponding to a molecular weight of 32×10^6.

BLOOD-FEEDING, FECUNDITY AND AGEING IN *AEDES AEGYPTI* VAR. *QUEENSLANDENSIS*

By DR. M. M. J. LAVOIPIERRE

George Williams Hooper Foundation, University of California Medical Center, San Francisco

IN *Aedes aegypti*, as in many other culicines, a blood meal is essential for the maturation of the eggs, but it does not appear to be necessary for survival, since, under experimental conditions, this mosquito will live for many weeks on simple carbohydrates, notably certain hexoses and disaccharides[1]. This is not peculiar to mosquitoes, for in a wide range of biting and non-biting Diptera the normal life-span is attained on a carbohydrate diet[2]; the protein meal, apparently, is basically related to reproduction.

Adult female *A. aegypti* var. *queenslandensis* reared from well-nourished larvæ usually require only a single blood meal for the maturation of their oocytes[3], the number of eggs which develop depending on the host from which the meal is obtained[4]. After the first blood meal mated females may bite again, but their avidity for blood diminishes markedly as the eggs mature, biting being minimal just before oviposition[5]. After egg-laying, avidity once again becomes pronounced, and the cycle is repeated. On the other hand, in the case of the unmated insects, biting activity is high throughout the gonadotrophic cycle, although the number of eggs maturing and the speed at which they develop is no less than that of the mated flies. The unmated females retain most of the mature eggs during the remainder of their lives, deposition of the small number laid being extended over many weeks[6]; none the less, avidity for blood continues to be pronounced for several weeks, diminishing gradually as the population ages.

Since these results were published, I have shown that the blood-feeding drive is apparently closely related to oogenesis and to vitello-genesis. Supernumerary blood meals taken by unmated females were abnormally metabolized, producing, particularly in the ovary, aberrant changes which were especially noticeable in older flies. Moreover, the protein meal shortened the life-span of the unmated mosquitoes: a comparison (Figs. 1 and 2) of the survival-curves of mated and unmated insects, offered daily meals on human subjects, shows that the mated flies survived much longer than those which were unmated. The increase in death-rate

Table 1. 50 per cent mortality and life-expectancy of, and the number of eggs (calculated as a percentage) oviposited by, several populations of (*a*) mated and (*b*) unmated females of *Aedes aegypti* var. *queenslandensis* offered blood meals (for 10 min.), daily and at intervals, over a period of many weeks. In the mated group three cages were set up, each with a random number of mosquitoes—individuals which had not fed when the first blood meal was offered (the numbers are indicated in brackets) were removed and discarded; in the unmated series 140 previously fed mosquitoes were divided into two equal groups

Whether mated or unmated	Frequency of feeding	No. of mosquitoes	50 per cent mortality in days	Life-expectancy in days after 1st blood meal	Further life-expectancy in days at age 35 days	No. of eggs laid at 50 per cent mortality (calculated as a percentage)
Mated	Daily	104 (3)	69·0	65·1	35·5	44,166
	Every 8 days	85 (12)	81·0	77·0	46·5	33,761
	Every 16 days	62 (10)	91·0	80·9	53·0	26,613
Unmated	Daily	70	38·5	38·6	11·4	1,949
	Every 16 days	70	39·0	40·3	14·3	1,820

seems related to the metabolism of the blood meal, since virgin females of *A. aegypti* var. *queenslandensis* slightly outlive mated females when the populations are maintained on a sucrose diet alone[7]. In the case of certain other insects, however, for example, *Drosophila obscura* and *Periplaneta americana*, which discriminate much less than *A. aegypti* in their food-seeking, a diet which is responsible for high fecundity in mated females does not appear to reduce the life-span of the unmated females, which, indeed, live longer than their mated fellows[8].

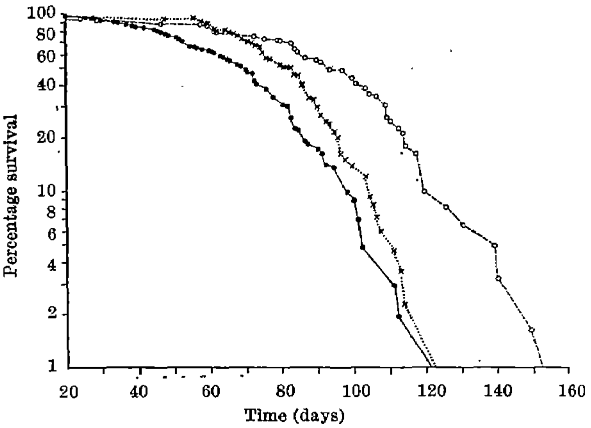

Fig. 1. Survival curves for comparable groups of mated *Aedes aegypti* var. *queenslandensis* offered blood meals daily ●, every 8 days ×, and every 16 days ○, plotted on semilogarithmic co-ordinates. The three groups were offered the initial meal on the same day

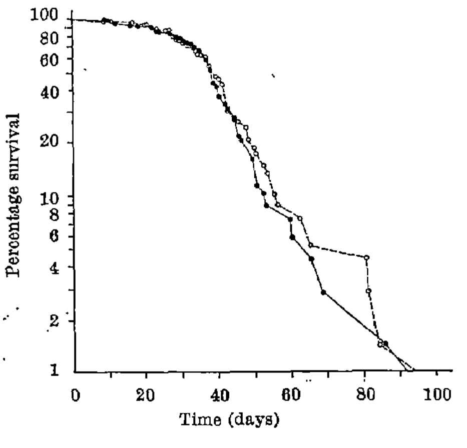

Fig. 2. Survival curves for comparable groups of unmated *Aedes aegypti* var. *queenslandensis* offered blood meals daily ●, and every 16 days ○, plotted on semilogarithmic co-ordinates. The two groups were offered the initial meal on the same day

Decreasing the frequency of feeding apparently scarcely influences the death-rate of the unmated females. The survival curves of two comparable populations, one fed daily and the other every sixteenth day, were found to approximate very closely (Fig. 2): calculations for life-expectancy differed little, a t-test giving $P > 0{\cdot}1$ and $< 0{\cdot}2$. In both populations the number of eggs deposited at 50 per cent mortality was small and almost the same (Table 1).

When, however, three comparable groups of mated mosquitoes were offered blood meals, daily, every eighth day, or every sixteenth day, the results were entirely different. The death-rate of the mated insects increased significantly with increased frequency of feeding, a t-test applied to the daily and 16-day groups giving $P = 0{\cdot}001$ (Table 1, Fig. 1). Associated with the more frequent opportunities to feed was a definite augmentation in the number of eggs laid, the daily-fed group laying 27 and 66 per cent more eggs than the eighth- and the sixteenth-day groups respectively at 50 per cent mortality.

These observations appear to indicate that while increased frequency of blood-feeding in mated females of *A. aegypti* var. *queenslandensis* allowed to lay eggs was accompanied by a marked increase in the death-rate of the mosquitoes, the effect seemed to be associated with augmentation in fecundity alone, for, in unmated females, which laid few eggs, increased feeding had no significant effect on the death-rate.

The results also suggest that the number of eggs laid by the mosquito is a parameter which may be of value when the probability of survival of mosquito populations both in the laboratory and in Nature is computed. The number of eggs laid depends on the number of ovipositions, and since the number of times a mosquito has oviposited can now be determined[9], the findings reported in this article may be of practical significance to investigators working on the dynamics of field populations of mosquito vectors of disease.

BRAIN WAVES AND 'BLOOD WAVES'

By HENRY R. PANTEK

Kresge Medical Research Institute, University of Michigan, Ann Arbor

IN search of an efficient method for localizing brain tumours, the temperature records in Fig. 1 were obtained from a normal female head with a modified Beckman d.c. breaker amplifier, a Leeds and Northrup paper recorder, and a copper-constantan thermocouple. The broken-line curve was taken with the thermocouple attached to the right temple and the solid line with it attached to the middle of the forehead about 4 cm. above the glabella. This latter record was obtained 24 hr. after the first. The subject sat comfortably in an arm-chair and was asked to relax with her eyes shut. At the first points *O*, about 5 min. later (the first 4 min. of the record is not shown in Fig. 1, the points *O* are shown at 0·6 min. later) the subject was asked to open her eyes and was immediately handed a multiplication problem. She finished multiplying a five-digit number by a four-digit number at the points *F* some 2 min. later. In this interval a large temperature change was noted. At points *C* she was asked to close her eyes and completely relax, and at the second points *O* was told to open them again. However, on the solid-line curve at point *O* she was given a second multiplication problem, whereas on the broken-line curve was engaged in a spirited conversation. From points *C* to *O* a temperature drop of about 3° occurred.

After examining the curves, it was decided that these variations in temperature or 'heat waves' were due to a change in blood-flow in these regions. Since it is known that problem solving is accompanied by fast electroencephalographic (EEG) waves[1] it was thought that these brain waves may be variations in potential between sites due to ions in motion in the blood vessels. That is, brain waves may actually be principally 'blood waves'. To test this electrohæmodynamic hypothesis a model was constructed as shown in Fig. 2, to simulate a simple blood vessel system. A 3-l. glass bottle filled with physiological saline was connected by 5 mm. inside diameter (all diameter dimensions given are inside diameter unless otherwise indicated) rubber tubing to a piece of polyethylene tubing 10 cm. long with a diameter of 2 cm. A hypodermic needle stylet *C* was forced half-way into this large tube in contact with the saline solution to serve as an EEG reference point or earth. The tube *B* was then connected to a glass *Y* connector *D*, and the two arms were each connected to No. 18 hypodermic needles. A duplicate of *D* connected to vessel *J* was coupled to it by two 20-cm. pieces of No. 18 (approximately 1 mm. diameter) polyethylene tubing via the No. 18 needles. Four size 35 suture wires (*E*, *F*, *G* and *H*) were forced into this small tubing 7·5 cm. apart to make contact with the saline solution. Wires *E* and *F* were connected to a flashlight battery to simulate d.c. potentials that may be present at a site. Wires *G* and *H* were connected to an EEG channel. The rubber tubing leading to the receptacle *J* had a diameter of 3 mm. The manometer *M* and the 3-mm. tubing *K* were connected by a glass *T* to bottle *A*. Whenever *K* was left open the solution in *A* was at zero pressure (or atmospheric pressure) and pressure and vacuum variations were applied by inhaling or exhaling into this opening. The records shown in Fig. 3 were obtained from this system.

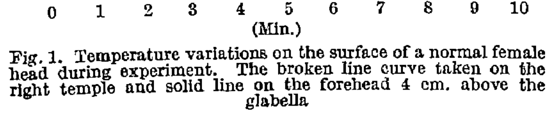

Fig. 1. Temperature variations on the surface of a normal female head during experiment. The broken line curve taken on the right temple and solid line on the forehead 4 cm. above the glabella

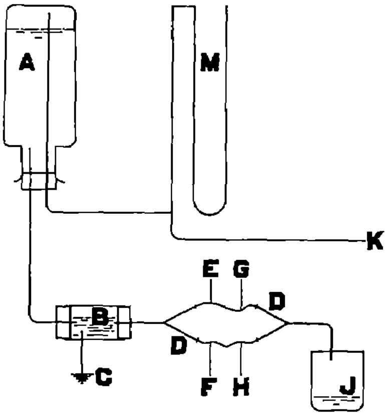

Fig. 2. Schematic representation of simulated simple blood vessel system

At atmospheric pressure the normal flow of the saline solution from bottle *A* through the system and finally into the container *J* was 60 c.c./min. The recording speed was 30 mm./sec. and each recording in Fig. 3 was obtained successively in a single experiment. Record *A* was obtained by creating a 20-mm. vacuum in bottle *A* and pinching off the opening at *K* with a clamp. This record occurred 144 sec. after the application of the vacuum. At this time the vacuum increased to 40 mm. due to the saline solution running out. It was observed that the waves at 3 per sec. are due to the formation and severing of drops at the end of the rubber tubing in container *J*. From an initial rate of about 6 drops/sec. and amplitude of 40 μV. the flow fell to 3 drops/sec. and the amplitude increased to 180 μV. This record might be compared with a left and right parietal petit mal record of a 9·5-year-old male child[3]. Record *B* is a

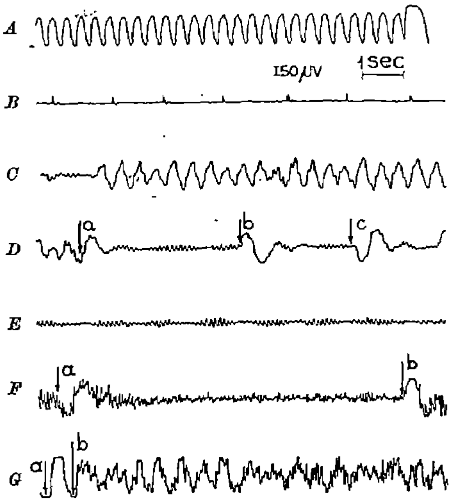

Fig. 3. Records obtained from simulated simple blood vessel system. Consecutive records from a single experiment

simulated heart beat which was obtained without a d.c. potential between E and F in Fig. 2. In this and later records the tube in container J was submerged below the level of the solution in J. The pressure at K was alternately built up to 30 mm. and suddenly released at intervals indicated by the distance between the spikes. When the pressure was alternately increased to 40 mm. no increase in amplitude of the spikes occurred, but remained at about 35 μV. Record C was obtained by squeezing the tube K about twice per sec. with the thumb and finger while it was clamped and the vacuum in A had slowly built up to 40 mm. Preceding this record there was a predominance of 10/sec. wave-forms with an amplitude of about 25 μV. while the vacuum was slowly building up. Occasionally big slow spikes and slow waves of 2–3 per sec. would appear. Amplitude modulated 9/sec. wave-forms such as in record E began appearing at about 33-mm. vacuum which occur in practice in the occipital region normally at any age. Record C can be compared with that of an 8-year-old boy in very deep sleep[2]. Record D occurred about 100 sec. before record E and the slow waves were produced by squeezing tube K while maintaining a 40-mm. vacuum. This record followed C by 20 sec., and the tube was squeezed with thumb and finger at point a, released at b, and again squeezed at c. Such slow waves apparently occur during light sleep of an adolescent. Record F was obtained by applying a pressure of 20 mm., which was released at point a and applied again at b. This recording is similar to an attention record where the eyes are closed and later opened. Recording G was made by first applying pressure rhythmically at about 1·5 times per sec. to point b (only one wave-form at this rate is included in the figure) and suddenly changing the rate at point b to twice per sec. These waves are similar to the paroxysmal waves in petit mal[3].

It is interesting that the heart-beat was reproduced without a d.c. potential and the other records with a d.c. potential applied. I think that these phenomena should be investigated further *in vitro* and *in vivo*, since it may explain the apparent discrepancies that occur when EEG patterns are compared with the location of certain brain lesions[4], their absence in hypothermia[5], and their presence over the area of a hemispherectomy, as I have observed.

FACTS AND THEORIES OF SHAPE DISCRIMINATION

In a recent article[1] Sutherland attempted to evaluate three theories of shape discrimination (actually, they are theories of the coding of information about shape in the brain, none is a complete theory as it stands.) The three theories are: Sutherland's own theory, which he labels theory A (ref. 2); a recent theory of Deutsch's, labelled theory B (ref. 3); a theory of mine, labelled theory C (ref. 4).

In his evaluation of these theories, Sutherland makes some incorrect statements about theories B and C, and does not mention some evidence of his own which is opposed to his own theory. The purpose of the present article is three-fold. First, to re-examine the evidence presented by Sutherland and to show that the conclusions he draws from it are unjustified; secondly, to point out several weaknesses in theory A which are purely logical and have nothing to do with the degree to which any one of the three theories has been verified or otherwise; and thirdly, to present some fresh observations which support theory C, but which do not support theory A. The discussion of the first topic will be confined mainly to the arguments put forward in Sutherland's article[1], and to theories A and C only, since Deutsch has already replied to Sutherland's criticisms of theory B (ref. 5).

Evaluation in Relation to the Various Theories

Sutherland[1] lists twelve groups of facts in his evaluation. Those facts which support both theory A and theory C will not be discussed; those which are claimed to give support to A but not to C will be discussed in the order and with the numbering given in Sutherland's article. His Fig. 1 is reproduced, together with the horizontal and vertical outputs of theory C, to clarify the ensuing arguments. A word about the outputs of theory C is in order. The two co-ordinates for an output are: on the ordinate, size of impulse; on the abscissa, time of occurrence. Thus each output is characterized by the sizes of the impulses generated and by the temporal pattern in which they occur, and either of these properties is sufficient to make an output distinctive and discriminable. Only in cases where there is little or no difference in *both* properties for both horizontal and vertical outputs respectively does the theory predict confusion of the associated shapes. The impulses are generated by a system which sums the extent of the contours of a shape on horizontal and vertical co-ordinates over a two-dimensional array[4].

(4) *Discrimination of broken vertical rectangle.* Sutherland points out that this shape (Fig. 1*a*) will be treated as a vertical rectangle in theory *A*, which is correct; but as a horizontal rectangle in theory *C*, which is incorrect, as can be seen by comparing the outputs for this shape with the outputs for vertical and horizontal rectangles shown in Fig. 2. This suggests that Sutherland has misunderstood theory *C*. The octopus and the rat both treat the broken vertical rectangle like a vertical rectangle, but Sutherland's assertion (p. 842): "... This result supports *A*, but is evidence against both *B* and *C*" is plainly incorrect.

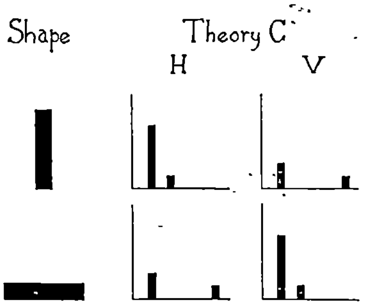

Fig. 2

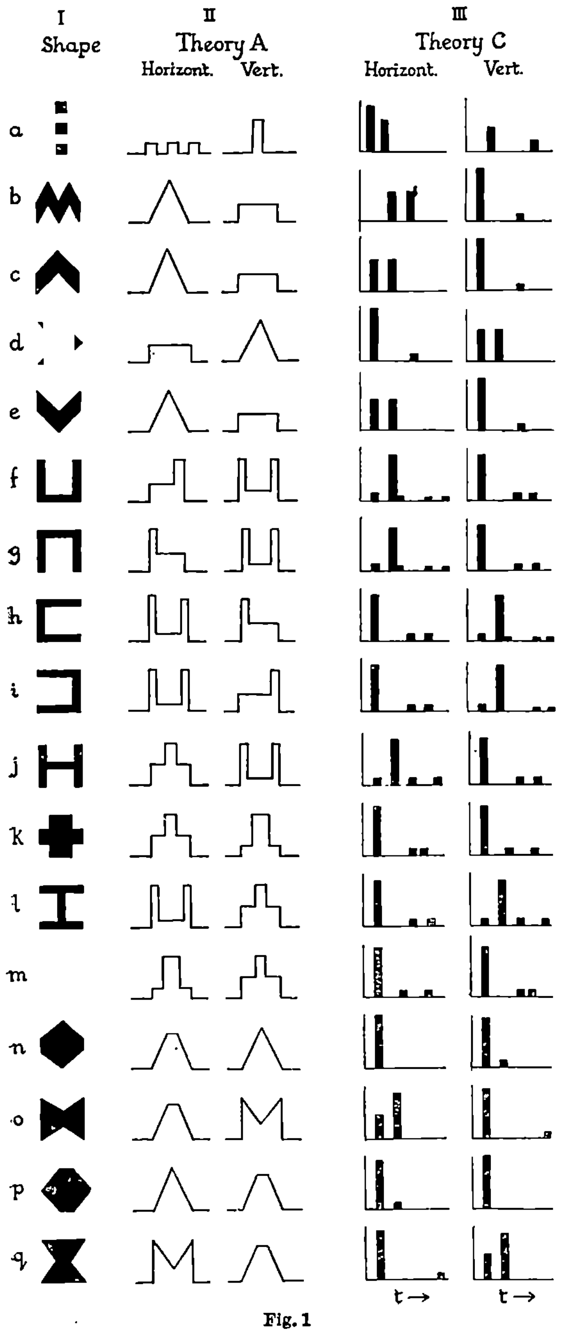

Fig. 1

(6) *Discrimination between diamond and oblique rectangles.* Sutherland is correct in stating that these figures should be indiscriminable on *C*, and since they can be discriminated by the octopus, he considers this a crucial test of theory *C*. However, inspection of his Fig. 2*a* shows that the diamond and rectangle used in his experiment are different in area (the dimensions reported elsewhere[6] are: square 5 cm. × 5 cm., rectangle 2 cm. × 10 cm.), and since he used 'filled in' shapes, or surfaces, rather than contours, it is obvious that the discrimination could be a simple brightness discrimination. Although some of the subsequent transfer tests suggest that discrimination was not based on brightness differences alone, no direct test of the effect of the brightness difference was made. As it stands, this finding can scarcely be considered a test of theory *C*, much less a crucial test.

(8) *Discrimination between shapes b, c, d and e* (*Fig. 1*). Theory *A* predicts that *b* and *c* should be indiscriminable, but they are discriminable. This is evidence against theory *A*, and to save it Sutherland has to introduce an additional assumption (ref. 1, p. 844 (1)). Inspection of the outputs for theory *C* in Fig. 1 shows that: (i) *b* and *c* should be discriminable, but with difficulty; (ii) *c* and *d* should be readily discriminated; and (iii) after training on *c* and *d*, *b* should be treated like *c*. Sutherland found all these three to be true, so his evidence supports *C* rather than *A*, since all three can be predicted from *C* without introducing additional assumptions. The lack of discrimination between *c* and *e* supports *A* and *C* equally.

(10) *Discrimination between up-down and right-left mirror images.* The fact that discrimination is possible appears to refute *C*, since inspection of the outputs for the pairs of shapes *f*, *g* and *h*, *i* (for example) shows that they are identical for each pair. However, Sutherland's use of filled-in shapes again makes his mirror-image experiments a poor test of *C*. While the overall brightness of shapes *f* and *g* is the same, for example, the distribution of brightness is different. Thus this pair could be discriminated on the basis of 'brighter above' (*g*) versus 'brighter below' (*f*). This possibility should at least be examined experimentally before adducing this evidence as a ground for refuting *C*. It may be noted that where there is

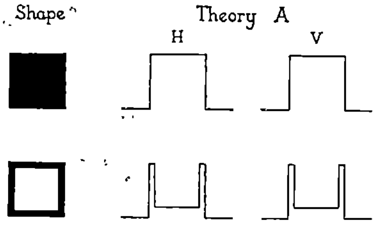

Fig. 3

not such an obvious difference in brightness distribution (as in shapes *c* and *e*), there is also no discrimination between the pair.

(12) *Discrimination of the pairs of shapes j, k; l, m; n, o; and p, q,* Inspection of the outputs for theory *C* shows that all four pairs should be easily discriminable, whereas theory *A* predicts that the pairs *j*, *k* and *n*, *o* should be less discriminable than the others, on the assumption of greater resolving power for the horizontal outputs (ref. 1, p. 843). Even if this assumption were incorporated (as it could be) in *C*, to account for the fact that horizontal rectangles of different extents are more readily discriminable by the octopus than vertical rectangles of different extents, this would still leave the pairs *j*, *k* and *l*, *m* equally discriminable, since both differ in both horizontal and vertical outputs in *C*. The same argument applies to the pairs *n*, *o* and *p*, *q*. So here are two cases where *C* yields a correct prediction, and *A* a false one, since all the pairs are discriminable. The remainder of the experimental findings are neutral, that is, equally explainable on either *A* or *C*.

Sutherland states (p. 843): "Theory *C* yields incorrect predictions throughout with the exception of some of the initial findings". In only two cases (diamond and oblique rectangle; mirror images) do Sutherland's experimental findings tend to refute *C*, and in both cases the evidence is vitiated by failure to implement a simple and obvious control condition. In five cases under (8) and (12) *C* yields a correct prediction, where *A* yields a false one; so Sutherland's evaluation of his theory as superior to *C* can scarcely be upheld on the evidence of his own experiments. Moreover, one piece of his own evidence not quoted by Sutherland is the fact that, apparently, the octopus transfers from discrimination of filled (surface) shapes to outlined (contour) shapes[6]. Theory *A* is a theory of surface discrimination, not one of contour discrimination. For theory *A* a contour shape shares nothing in common with a congruent surface shape except its outline, and the theory must deal with that outline as a 'surface'. The resulting outputs will be very different from the outputs for a surface shape. This is illustrated in Fig. 3, which shows the theory *A* outputs for a square, (*a*) as a surface shape, and (*b*) as a contour shape. Quite evidently the two are very different, and no transfer should occur from one to the other.

Logical Weaknesses in Theory *A*

Sutherland gets around this difficulty by assuming ". . . that some sort of filling-in mechanism occurs with outline shapes, although no attempt will be made to specify how this takes place"[6]. This is scarcely an acceptable avenue of escape from what looks like a crucial objection to theory *A*. In making this assumption, Sutherland specifically eschews any interpretation of theory *A* as a theory of contour discrimination. While this removes some ambiguity from his original statement of the theory[2], it leads one to question its plausibility. There are good reasons, both logical and factual, for supposing that contour properties are more important in shape discrimination than surface properties. Logically this is so, because the property of 'shape' in a stimulus display entails the property of 'contour' in that display, but does not entail the property of 'surface' as this has been used in the literature, to describe a difference in brightness, hue or saturation between the interior and exterior of a closed contour. A discriminating system based on contour properties is thus more general than a system based on surface properties. Practically, it seems unlikely that shape discrimination could be based only on properties of surface extent and not contours, since it has been shown for at least two types of visual system that surface and contour have different central representations[7,8]. (Young's demonstration of a marked layering of the plexiform zone in the octopus[9] suggests that the various layers might mediate different aspects of a stimulus display, such as surface and contour). Although there is no direct evidence to show what the relations are between these two types of representation, the preceding argument about the greater generality of contour discrimination suggests that, in the absence of physiological or behavioural evidence that 'filling in' occurs, the proper strategy to pursue is to assume that discrimination of shape is based on contour properties. Experimenting with outlined shapes should then yield results uncontaminated by the possibility of competing or confounding computations based on surface extent (this was pointed out some time ago in assessing earlier work on visual discrimination of shape[4]).

A further weakness of theory *A*, which has been pointed out previously[10], is that the manner in which row and column outputs are analysed is vague. The statement of theory *A* (ref. 2) suggests that this further analysis involves not only the magnitudes of the outputs but also their spatial distributions. For example, theory *A* outputs for shapes *f* and *g* in Fig. 1 are identical except for the fact that the peaks in the horizontal outputs occur in different positions relative to the total extent of the horizontal outputs: to discriminate between the pair, the analyser must register this difference. That is, since the recognition of shapes is supposed to occur independently of their position in the two-dimensional array, the analyser must be capable of registering differences in spatial patterns independently of their position ('peak to the right', or 'peak to the left' must be registered independently of whether these occur to the left, to the right, or in the centre of the horizontal output, for example). This problem, of recognizing a spatial pattern independently of its position, has always been a major difficulty for neural theories about the recognition of shapes (a difficulty which is overcome, incidentally, in theory *C*, by transformation of spatial into temporal patterns). An analyser which would perform this function would be of considerable theoretical importance, but Sutherland's statements on the topic have been too nebulous to make it possible to decide how the analyser is supposed to work, or whether it can really cope with the problem of registering spatial patterns in different positions. Further, it is difficult to see what the point is of postulating a two-dimensional array to separate horizontal and vertical components of a shape before

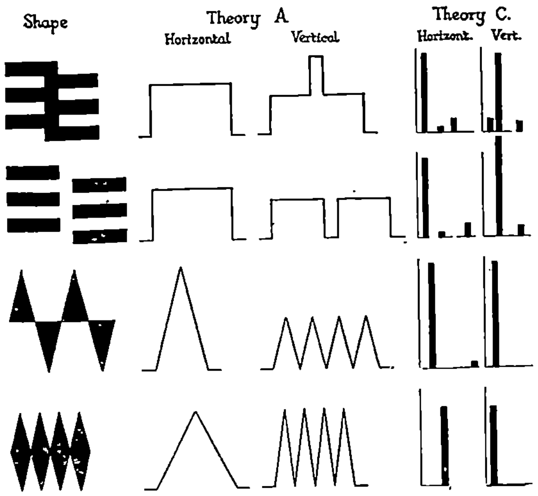

Fig. 4

input to the analyser. If the analyser has the properties required to deal with the analysis of the separate outputs of theory *A*, it should have the requisite properties for analysing shapes without prior separation into components, namely, the ability to register differences in spatial pattern independently of location.

Some New Evidence

In an attempt to gain some clear evidence in favour of either theory *A* or theory *C*, experiments were performed with rats and squirrels using the two pairs of shapes shown in Fig. 4. It can be seen by inspection of the associated outputs that theory *A* predicts good discriminability for the pair *a*, *b* and poor discriminability for the pair *c*, *d*: theory *C* predicts the reverse. These experiments will be reported in detail elsewhere; briefly, the results support theory *C* for both shapes in both rats and squirrels. In both cases there was a difference of discriminability in favour of the pair *c*, *d*. In the squirrel experiment the results are not quite conclusive, since only a small number of animals was available, and the experiment was in the nature of a pilot investigation. In the rat experiment, however, a *t*-test on the scores was significant ($P <$ 0·01), and in favour of theory *C*. It may be noted here that Sutherland has frequently reported significant differences for groups of animals in terms of a χ^2 test with one degree of freedom. Such a test is not appropriate as a test of differences between group means, since it takes no account of variability from one subject to the next. Thus, in addition to the difficulties already mentioned, a number of the results reported by Sutherland are based on inadequate statistical analysis; although the direction of the results is unambiguous, their conclusiveness is questionable.

The shapes used in the present experiment were surface shapes, rather than contour shapes. This may seem surprising, in view of the criticisms of the use of surface shapes made earlier. I used such shapes for the following reasons: (*a*) surface shapes should favour theory *A*, since that theory is a theory of surface discrimination, and it should involve complicating factors for a contour discrimination theory (namely, *C*); and (*b*) if (as seems scarcely possible) theory *A* could be interpreted as a contour discrimination theory, the use of surface shapes involves equal difficulties for both *A* and *C*. Thus, the use of surface shapes should either favour theory *A*, or be neutral between *A* and *C*: had contour shapes been used, the argument could have been put forward that the experiment was biased in favour of C.

Conclusion

To sum up: I believe that Sutherland's evaluation of theories *A* and *C* is faulty, and that the evidence he quotes supports theory *C* rather better than theory *A*. The faulty evaluation is in part due, apparently, to a misunderstanding of theory *C*. There are difficulties in his evidence for both theories, and either theory can only be saved by making additional assumptions.

Logical difficulties in theory *A* have been examined. Although the theory has not been stated clearly, it is evidently a theory which bases analysis on surface extent only, and not on the contours of figures. It seems unlikely that shape should be discriminated only in terms of surface and not in terms of contour, and physiological evidence to support this statement is available. This same evidence makes it perfectly plausible to suppose that contour can be 'abstracted' from surface shapes, and discrimination based on this abstracted information.

The analysis of horizontal and vertical outputs for theory *A* has been described quite as vaguely as the actual generation of those outputs, and to make the sort of analysis proposed comprehensible a far more thorough description is needed. Justification for separation into horizontal and vertical components is lacking, and this is a further weakness in the theory.

New evidence described here favours theory *C* over theory *A*, although the experimental conditions were biased in favour of *A*.

One may conclude by stating that neither on empirical nor on logical grounds is theory *A* superior to theory *C*. The logical weaknesses in theory *A* indicate that it should either be dropped or re-stated in a clear and unambiguous way.

[10] Dodwell, P. C., *Nature*, **179**, 1088 (1957).

IN the preceding communication Dodwell takes me to task for the way in which I interpreted[1] my own experimental results on shape discrimination by *Octopus*. I agree with some of his general remarks. For example, he emphasizes at the outset that no complete theory of shape recognition in any species has yet been proposed. All he or I have suggested are ways in which information from patterned visual stimuli may be coded at some stage in the nervous system. These suggestions as to coding have been made to account for the relative difficulty animals have in discriminating between different pairs of shapes, the confusions they make between shapes, and the relative similarity of different shapes for a given species as revealed by transfer tests. A 'complete' theory would have to account for all the available evidence and would also be concerned not merely with how the stimuli are coded on the input side but exactly how the input as coded is further analysed and how the resulting neural output governs the responses made by the animal.

Unfortunately, I cannot agree with most of Dodwell's more detailed points. Many of them are based on assertion rather than argument. For example, he states that I use χ^2 to test for the difference between the performance of groups of animals, and rightly points out that this is the wrong statistic: in fact, in all papers written by me the significance of the difference between the performance of different groups of animals being trained to discriminate between different shapes has been evaluated by *t*-tests or analysis of variance and not by χ^2. Again, Dodwell suggests that the first stage of my own theoretical analysing mechanism (namely, breaking a shape up into its horizontal and vertical components) is unnecessary, since if the further analyser which analyses these projections "has the properties required to deal with the separate outputs of theory *A*, it should have the requisite properties for analysing shapes without prior separation into components": this is a complete *non-sequitur*. It is hard to see why Dodwell supposes that a mechanism which can analyse outputs on a one-dimensional neural array must be capable of analysing a two-dimensional array, and even if this were true there is no reason to suppose that the nervous system performs the complete analysis of shape in one stage.

Unfortunately, Dodwell does not state his own theory in the accompanying article. It may be helpful to the reader to have a brief statement of this theory[2]. He suggests that excitation representing the contours of shapes is projected on to a square array of cells in the brain. Impulses sweep across this square array in directions corresponding to the visual vertical and horizontal. Impulses travelling in either direction are said to be slowed down when they cross an area already excited by neural activity resulting from a contour present at the retina. The extent to which an impulse is slowed down is said to depend on the direction of the contour in relation to the direction in which the impulse is travelling. All impulses travelling in one direction are fed into a final common path: activity in this pathway represents the number of impulses arriving per unit of time. This theory is highly ingenious, but does not seem particularly plausible on neurological grounds, since it must involve some mechanism to synchronize the start of successive travelling waves of impulses. The pictures Dodwell presents in his Fig. 1 (column III) represent the outputs given by different shapes in the final common pathways: unfortunately, since he does not tell us how these outputs were derived, we have to take them on trust and many of them do not appear to conform to the rules he gives in his previous paper[2] (for example, those for shapes *b, c, j, l, n, o*). This doubt about how his outputs are derived makes it impossible to discuss some of the arguments based on these outputs. It may, however, be useful to discuss the crucial issues under each of Dodwell's main headings.

Evaluation in Relation to the Various Theories

Dodwell agrees that the ability of octopuses to discriminate between a diamond and an oblique rectangle constitutes a crucial test between his theory and my own. He is surely mistaken, however, when he says that the experiment I actually performed on this is inconclusive because I failed to equate the diamond and the rectangle for total brightness. He argues that since the area of the diamond used was 25 sq. cm. and the area of the rectangle was 20 sq. cm., it is possible that animals may have learned to discriminate between them in terms of the difference in the total brightness of each. This possibility is discussed in my paper reporting this experiment[3], and careful controls were run to test whether animals had been discriminating between the shapes in terms of their difference in brightness. Three findings reported in that paper rule out this interpretation: (1) If, after animals have learned the discrimination they are shown a rectangle with a *larger* area than the diamond, then, if they are responding in terms of brightness, they should respond to it in the way in which they had learned to respond to the diamond. When a large rectangle was shown to animals, they continued to respond to it in the way in which they had formerly responded to the original rectangle. (2) Similarly, when a diamond of *smaller* area than the original rectangle was shown, they continued to respond to it as they had done to the original diamond. (3) Animals were originally trained with white figures shown against a grey background: they continued to discriminate between a diamond and an oblique rectangle when they were presented with black shapes against the same background. The brightness of the black diamond was less than that of the original white rectangle. Despite these findings, Dodwell writes, "no direct test of the effect of the brightness difference was made".

Of the remaining points raised by Dodwell in this section, he is correct in saying that his theory (as well as mine) predicts transfer from a vertical rectangle to a broken vertical rectangle (*a*, in Fig. 1), and I was mistaken in supposing that it could not[1]. His other arguments, however, are vitiated by a failure to take into account the results of transfer tests. Thus, when octopuses are trained to discriminate between shapes which differ markedly in amount of contour (for example, shapes *j–q*), the ways in which they effect transfer show that something more is involved than an analysis along the horizontal and vertical axes. This means that no theory based merely on an analysis along these axes will account for all the results, and hence it is necessary to postulate some further analysing mechanism at work.

Logical Weakness in Theory *A*

Much of this section is taken up with a general accusation of vagueness in my own theory. As pointed out already, this charge is justified but applies to all theories of shape recognition hitherto proposed. However, it should be remembered that my own theory has been able to yield many detailed predictions which could be and have been tested, and that these predictions were rigorously derived from the theory Dodwell does not deny. As Dodwell rightly observes, the greatest area of vagueness lies in the fact that further mechanisms for analysing the output from rows and columns (that is, the shape of the 'projections' shown in Fig. 1 of Dodwell's article) have not been specified (for some suggestions see ref. 4). It would, however, be idle to speculate about this problem in default of evidence which would allow one to choose between alternative possibilities, and until the theory has received more thorough testing at its present level of complexity. Dodwell himself has not attempted to specify how the outputs yielded by his own mechanism are analysed.

He raises the important question of whether shapes are analysed in terms of their surface area or whether they are analysed in terms of their contours, and writes that my suggestion of a filling-in mechanism is vague. It is of course true that the contours of a shape are of importance in shape recognition, but what I am arguing is that it is the distances between contours that is important, not merely their orientation. Dodwell's mechanism operates primarily on the direction of contours in visual space: it does not analyse the distances between contours. It is for this reason that it predicts that animals should be unable to discriminate between a diamond and an oblique rectangle. All the contours of these figures run at 45° to the vertical and it is possible to draw the figures with the same total amount of contour as one another. It seems certain that, in discriminating between shapes, animals take account of the separation between contours and not merely of the directions in which they run, and for this reason Dodwell's theory is implausible. According to my theory, the octopus computes horizontal and vertical distances between contours: this would involve a filling-in mechanism for outline figures (incidentally, transfer to outline figures by octopuses is poor and sometimes non-existent[3,5]). It is important to be clear that a mechanism which operates *solely* on contour does not avoid the difficulties inherent in a filling-in process: thus if all contours present in a shape are analysed, animals that have learned to discriminate between unfilled outline figures should not effect transfer to the same figures with further contours inscribed within them. Evidence on this is lacking for the octopus, but Lashley[6] has found that rats show excellent transfer in just these circumstances. Thus a theory such as Dodwell's would need a 'blotting-out' mechanism to enable animals to disregard internal contours: this would be as complex as a 'filling-in' mechanism and indeed logically the two mechanisms reduce to the same thing.

Some New Evidence

In his final section Dodwell cites an interesting experiment he performed on rats and squirrels as providing evidence in favour of his own theory and against mine. He asserts that of the shapes shown in his Fig. 4, my theory (A) must predict that a and b would be more readily discriminable than c and d, whereas his own predicts greater discriminability of c and d than of a and b. These predictions are made on the basis of the outputs yielded according to the two theories and these outputs are shown in Fig. 4. The prediction Dodwell makes hinges on the difference between the outputs of a and b under my theory (A) being greater than the difference between the outputs of c and d, and vice versa under his theory (C). Examining the outputs in question as shown in Fig. 4, it is quite impossible to say under either theory whether the outputs of a and b are more or less different from one another than those of c and d: the reader can verify this for himself by inspection of this figure. Hence Dodwell's results, although of interest in their own right, are inconclusive with respect to the two theories under discussion. In order to say whether the outputs are more different for one pair of shapes than for another, it would be necessary to specify how the outputs themselves are analysed, which—as Dodwell himself points out—has not been done. Both theories can be made to make predictions, but only where the output for one pair of shapes is the same and the output for another different: Dodwell makes this point at the start of his section on evaluation, but he appears to have lost sight of it in designing a test between the two theories.

Conclusion

It is perhaps worth emphasizing why I have made no attempt in the above to deal individually with all the points raised by Dodwell: the details of this controversy are in fact in danger of obscuring the value of the experimental work on which the controversy is based. Dodwell and I are in agreement about the methods and aims of this type of work, and he clearly agrees that the evidence demonstrates that in the octopus an analysis of shape along horizontal and vertical co-ordinates is occurring. His own theory is valuable as a research tool, and this is all that I have claimed for my own. His theory prompted me to undertake the experiment on diamonds and oblique rectangles mentioned above, and this experiment yielded results of considerable interest irrespective of the rights and wrongs of any particular theory. The real importance of this type of experimental work lies in two aspects: (1) It demonstrates that it is possible to put forward hypothetical neurological mechanisms to explain behavioural findings, and that these mechanisms can be tested at a behavioural level. Disagreement arises at the present moment because none of the theories proposed has received sufficient systematic testing, and also none of the theories is complete. (2) Perhaps more important, the findings that have been obtained must eventually be linked with findings on the neuroanatomy and neurophysiology of the optic pathways. Only by having data on the functions mediated by these pathways will it be possible to interpret the meaning of the neuroanatomical structures and neurophysiological relationships which are at present being uncovered (cf. Young[7]). The final verification of any theory of shape discrimination must wait on further knowledge of this sort.

The work discussed in this article forms part of a project on "Stimulus Analysing Mechanisms", which is financed jointly by the American Office of Naval Research (Contract N 62558–2453) and the Nuffield Foundation. I am grateful to these bodies for their financial support.

LETTERS TO THE EDITORS

GEOPHYSICS

Connexion between Micropulsations and the Ionosphere

DUFFUS has recently pointed out a connexion between P_c occurrence and the F-region[1]. Other workers[2] have found correlation between P_t and f_0F_2 and it can reasonably be asserted that the ionosphere is a major factor in the transmission path by which these characteristic geomagnetic micropulsations are observed at ground-level. Recent work here has offered some further evidence on this subject.

For the purpose of this investigation P_c are defined as pulsations with a considerable element of continuity, lasting a number of hours, with periods between 10 and 60 sec., usually with a characteristic 'beating' appearance, and occurring predominantly in the day-time, although this last factor is not used for identification. P_t are short trains of oscillations with periods around 60 sec. which occur usually in otherwise quiet times at night. Fig. 1 shows typical examples of each class recorded on the Signals Research and Development Establishment's magnetometer. While it is generally accepted that these oscillations have their primary origin in solar emission, which by interaction with the Earth's atmosphere and magnetic field excites resonances in several possible ways[3-5], the exact manner of formation of each kind of pulsation is still unknown.

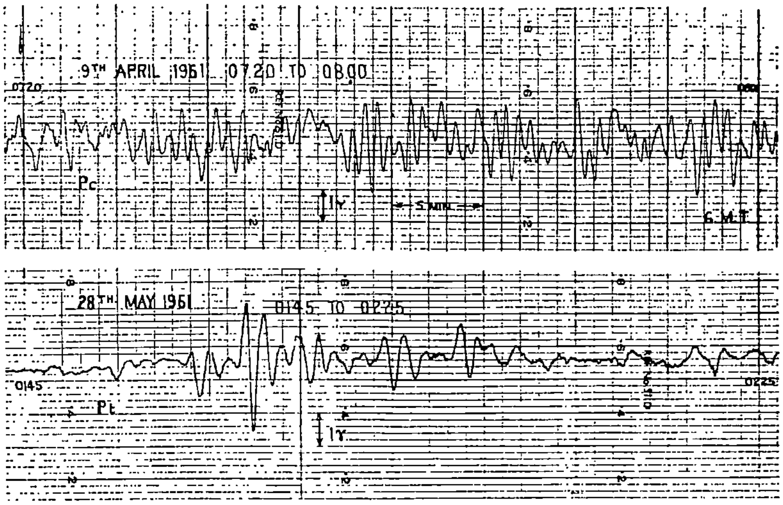

Fig. 1. Examples of geomagnetic micropulsations P_c and P_t observed at Christchurch, Hants

As part of a wider geomagnetic investigation, recording magnetometers have been set up at Christchurch (51° N., 2° W.) and Ascension Island (8° S., 14·5° W.), approximately 6,750 km. apart. Ascension is close to the geomagnetic equator so there can be no common lines of force with Christchurch. Inspection of simultaneous recordings from the two stations shows that P_t occur on both traces at the same time and with the same period, within the limits of discrimination of the system (Fig. 2). The amplitude at Christchurch is some 20–30 times that at Ascension. On the other hand, P_c, although occurring at about the same time and over the same frequency range, do not exhibit the same coherence (Fig. 3).

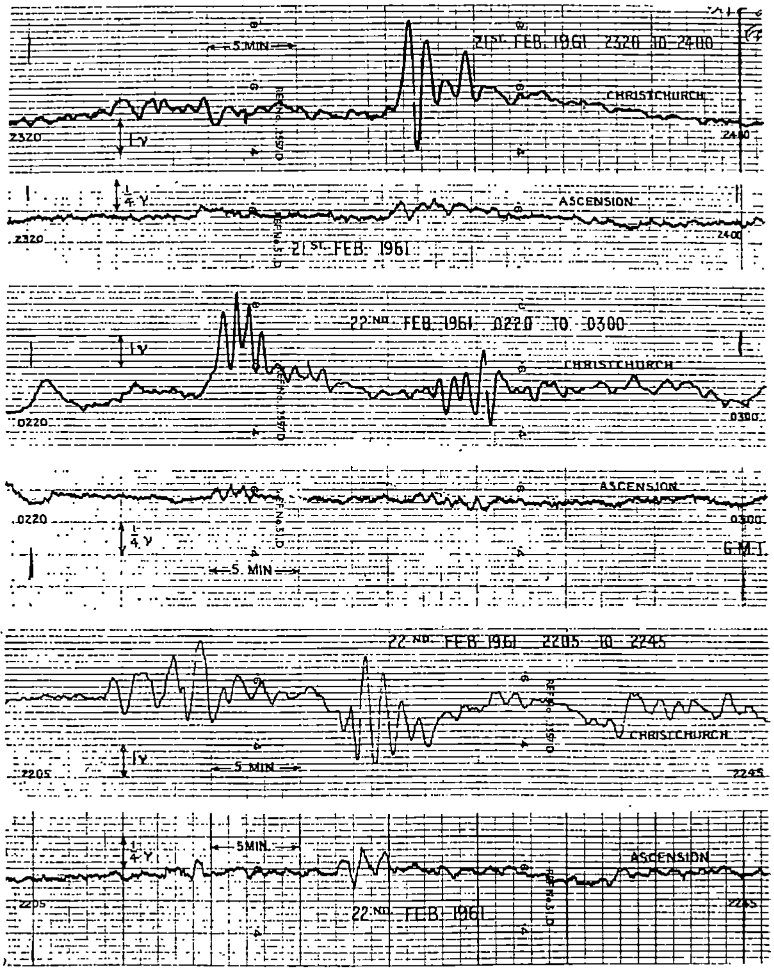

Fig. 2. Simultaneous recordings of micropulsations P_t at Christchurch, Hants, and Ascension Island

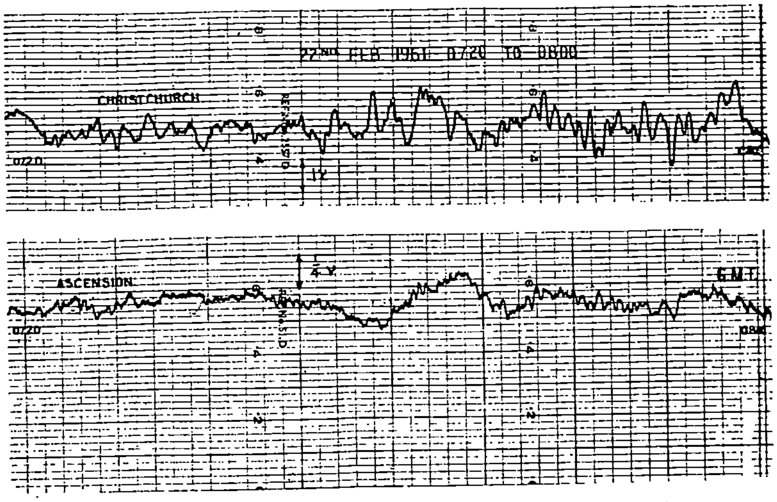

Fig. 3. Simultaneous recordings of micropulsations P_c at Christchurch, Hants, and Ascension Island

The seasonal variation of the start-up time (here defined as the time of the first fifth of the day's total active time) of P_c observed at Christchurch shows a definite correlation with sunrise (Fig. 4). This confirms the conclusion of Dr. Duffus that the low atmosphere has a modulating control over P_c and it also shows that this control varies markedly with latitude, in contrast to P_t.

The problem is to explain why P_t are night-time phenomena and are observed to be coherent over a great latitude-range, being of greater amplitude at high latitude, while P_c are recorded in the day-time and vary with latitude, both classes of pulsation being linked with the ionosphere. P_t may be oscillations of the outer atmosphere which are coupled into the ionospheric duct at the auroral belt, being propagated only in the low-attenuation night-time state of the ionosphere, while P_c may have a much more local and resonant transmission system, still originating in an outer atmosphere oscillatory mode. It is possible that part of their oscillatory content is inherent in the arriving corpuscular stream. Granulation waves of this frequency are known to exist in the photosphere[6-8].

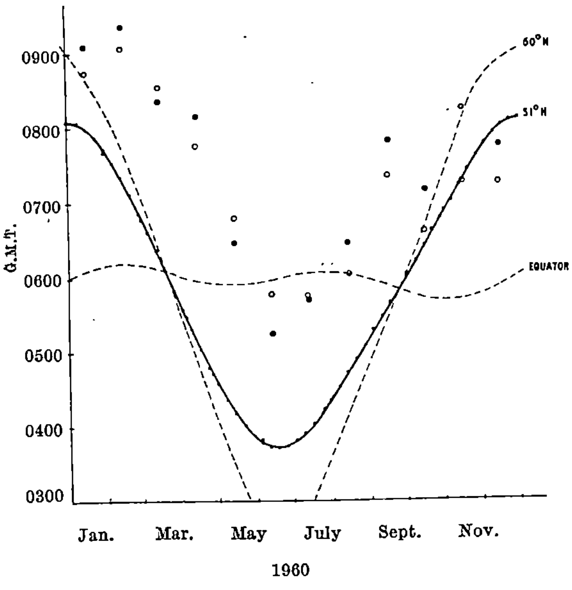

Fig. 4. Relation between mean monthly P_c start-up time and sunrise time at Christchurch, Hants. (Certain P_c are clear unambiguous displays. Weighed P_c have the hours of marginal P_c occurrence divided by 2 and added to the certain P_c.) Full line, sunrise 51° N.; ○, time of 1/5 days score weighed P_c; ●, time of 1/5 days score certain P_c; – – –, sunrise 60° N. and equator

Work at this Establishment is proceeding on the examination and classification of micropulsation activity together with a search for periodicities and cross-relationships. It is proposed to set up a magnetometer system with accurate timing between the stations and an increasing frequency coverage.

Acknowledgment is gratefully made to Mr. L. A. Brackstone of the Department of Scientific and Industrial Research at Ascension for his helpful co-operation.

Stress Effects on Thermoremanent Magnetization

Hall and Neale[1] have reported accurate measurements of the directions of thermoremanent magnetization acquired by rock specimens which cooled under stress in a low magnetic field. They observed small, but consistent, differences between the directions of thermoremanent magnetization in rocks cooled under stress and without stress, and suggested that their observations conflicted with our results[2,3], which indicated the absence of measurable differences in isotropic rocks. However, we consider that the experiments of Hall and Neale are consistent both with our results and with our conclusions, which may be summarized as follows.

In an igneous rock which is cooled under stress in a small magnetic field and then released from the stress, the direction of thermoremanent magnetization differs from the field direction by an angle which is controlled both by the stress and by the intrinsic anisotropy of the rock, but if the intrinsic anisotropy is very small, then the angular difference is also very small, regardless of the stress which was applied[4] (at least up to 1,000 kgm./cm.[2]).

In our experiments, rocks which were shown by torque-meter experiments[5] to have anisotropies less than about 2 per cent were cooled under directed stresses up to 1,000 kgm./cm.^{2} in the Earth's field. Within our measurement error of 2°–3° we found that the thermoremanent magnetization after release of stress coincided with the field direction. Quite different results were obtained with anisotropic rocks; for example, in a rock with approximately 60 per cent anisotropy which was cooled under stress, thermoremanent magnetization was induced at angles between 5° and 60° away from the field direction. It is important to note, therefore, that although Hall and Neale have reported more accurate measurements of the directions of such magnetization in rock specimens, they were using specimens with appreciable intrinsic anisotropies, such that the magnetization acquired in the absence of stress differed from the field direction by as much as 4°. According to Stacey's[5] analysis, this implies intrinsic anisotropy of at least 13 per cent, which can scarcely be described as 'slight'; a limit of 10 per cent was suggested[5] as acceptable in rocks used for palæomagnetism.

Further experiments are needed on the interaction of stress and the intrinsic magnetic anisotropies of rocks. It may be necessary to impose a more stringent limit than hitherto on the anisotropy, which is acceptable in rocks used for palæomagnetism.

FROM the results of our pressure experiments[1] and more recent measurements of susceptibility anisotropy it appears that this parameter is of negligible importance in the production of thermoremanent pressure effects.

The scatter of thermoremanent magnetization directions mentioned in our previous communication is a maximum for the coarse-grained Ob Lusa dolerite rock type. A group of ten finer-grained contact specimens from the Ob Lusa dolerite dyke show a scatter of only ±1·5° about the mean direction (the ambient field direction), while showing a pressure-induced rotation of moment six times larger than that of the coarser specimens. It is these latter specimens that show a maximum scatter of ±4° about the ambient field direction.

Measurements of susceptibility anisotropy at low fields have been made at Cambridge on all the specimens used in the investigation. Anisotropies of 1 per cent or less between axial values of initial susceptibility were found for all the rock types employed with the exception of that having pyrrhotite as a magnetic component.

ASTRONOMY

Holistic Approach to Selenology

THE proximity of exploration of the surface of the Moon demands a critical review of present selenological hypotheses. I wish to point out a defect inherent in modern selenological thought and to stress that there is a need for more information before developing contemporary theories more fully.

Theories of the formation of lunar craters may be divided into two classes: extrinsic (that is, impact—favoured by Baldwin and Urey) and intrinsic (that is, igneous—championed by Jeffreys and Spurr). Broadly speaking, the extrinsic hypotheses appeal to macroscopic features (for example, predominant circularity, the depth-diameter relationship, and the near-random distribution of craters) while the intrinsic theories appeal more to the finer features (including crater chains, summit craterlets, and crater polygonality).

The limitation to both approaches is that neither (in the first instance) distinguishes between primary and secondary features of the lunar surface.

Primary features are the large-scale structures as seen immediately after they were formed, and by secondary features I mean the alterations to the primary structures during their later life (this includes the effects of stress systems and erosion).

Consideration of the lunar grid system shows that large-scale stresses have been applied to the lunar surface during its history, and the effects of these stresses have been to obliterate information pertinent to the origin of the craters. In addition, completely new types of feature have arisen (for example, rill and valley systems) and some of these have been erroneously interpreted as primary features. Thus when one accepts the fact that the valleys radial to the Mare Imbrium are nothing more than a slightly more prominent element of the general grid system the collision hypothesis for the origin of this Mare loses considerable weight.

I would suggest, therefore, that the need at the present time is for a more expiscate approach. Many details of the lunar surface found recently do not fit in comfortably with any existing theories of crater formation, nor indeed with present ideas on secondary activity. We can only attempt to construct a complete theory when we have realized more of the properties of the features with which we are dealing.

PHYSICS

Use of a Different Type of Fluorescent Material as an Optical Maser

THE recent interest in the development of infra-red and optical maser systems has involved a number of different basic principles[1-3]. This communication is concerned with an alternative concept which utilizes the Stokes's shift associated with absorption and emission bands created by point defects in solids.

Preliminary calculations indicate that such a device can be made to operate.

We will be concerned with defect centres which possess non-overlapping absorption and emission bands. A specific example is the *F*-centre in potassium chloride, and this centre is selected as a representative example on which detailed calculations are performed since many of its properties are known. It is believed to consist of an electron trapped at a negative-ion vacancy. The broad absorption band associated with this defect centre shows a peak at 5600 Å. (2·3 eV.) while the emission band lies at 1·0μ. At temperatures below 80° K., the absorption-emission process is very nearly 100 per cent efficient so that for each photon absorbed one is emitted[4].

One can describe the principles involved in this suggested device by introducing a configuration co-ordinate curve (Fig. 1). The total energy is plotted along the ordinate, while the abscissa represents a general configuration co-ordinate. The frequency shift which occurs between the absorption and emission bands can be explained by referring to Fig. 1. The system in its ground-state at A undergoes the transition $A \rightarrow B$ when it is stimulated by the appropriate radiation. Then a radiationless transition, $B \rightarrow C$, follows, which lowers the vibrational level of the excited state. The system decays to a high vibrational level of the ground-state through the radiative transition, $C \rightarrow D$. Finally, the system relaxes back to A. Thus, the entire process may be visualized as a series of transitions between levels A, B, C and D. In view of the experimental data on emission, one may be certain that thermal equilibrium is established in the upper state before the emission of a photon. The non-radiative transitions from C to D are known to be small.

The relaxation times for the phonon-emitting transitions, $B \rightarrow C$ and $D \rightarrow A$, are approximately 10^{-12} sec., while the photon-emitting transition takes about 10^{-8} sec. Thus, it should be possible to make the ratio of populations in states C and D large by injecting radiation of the frequency $\nu_a = (E_b - E_a)/h$. On exposure to radiation of a second frequency, $\nu_e = (E_c - E_d)/h$, downward transitions are induced, resulting in the amplification of this second signal.

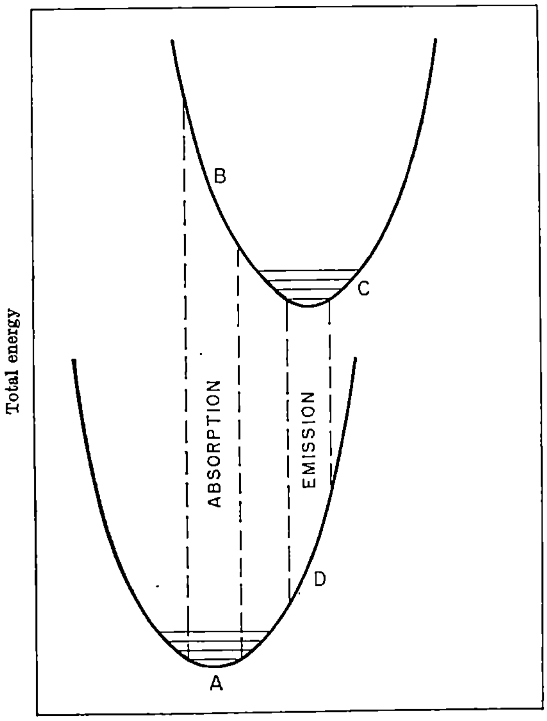

Fig. 1

The degree of amplification attained from such a system can be studied in terms of several parameters. The intensity of radiation emitted, I, is given by the relationship:

$$I = I_0 e^{\alpha' x} \tag{1}$$

where I_0 is the stimulating signal incident on the crystal, x is the distance the light travels and α' is a constant which corresponds to the absorption coefficient in the case of absorption. The absorption coefficient of a crystalline material containing defect centres is given by Smakula's equation as[5]:

$$\alpha = \frac{2}{9}\frac{e^2 f}{mc}\frac{(n^2 + 2)^2}{n^2}\cdot\frac{1}{\Delta\nu} N_a \tag{2}$$

where $\Delta\nu$ is the absorption band-width at half intensity; f is the oscillator strength associated with the defect centre; n_1 is the refractive index of the host crystal; N_a is the concentration of centres in the ground-state over that in the excited state; and e, m and c have their usual meanings.

If one now replaces $\Delta\nu$ with $\Delta\nu'$, the width at half height of the emission band, and N_a by N_c, one can adopt equation (2) to the case of emission since for any temperature of interest, $N_c \gg N_d$. In the case of the *F*-centre in potassium chloride:

$$\alpha' = 2{\cdot}7 \times 10^{-16} N_c \tag{3}$$

where f has been set equâl to 0·81. If $N_c = 10^{14}$, we find from equation (1) that x must be of the order of meters if one is to achieve a substantial gain; however, a measurable amplification could be attained if x were of the order of cm.

Consider next the power requirements to attain 10^{14} centres in state C. The life-time of this state in the absence of stimulating radiation is given by the einstein A coefficient as $5{\cdot}5 \times 10^7$ sec. when the effects of the dielectric are neglected. Hence, the life-time of the state C is $1{\cdot}8 \times 10^{-8}$ sec. and the required pumping power to maintain 10^{14} centres in state C is:

$$P = \frac{(h\nu)10^{14}}{1{\cdot}8 \times 10^{-8}} = 1{\cdot}27 \times 10^{22} \text{ eV./sec.} = 2{,}000 \text{ W.}$$

This is excessive if one hopes to maintain the required temperature; however, one may reduce this requirement by varying several parameters. The crystal dimensions could be reduced to 1 cm. × 1 cm. × 0·1 cm., thus reducing the power by a factor of 10. Furthermore, the device may be operated intermittently. Hence, the pumping power is reasonable for experimental purposes.

It should be pointed out that heavy *F*-centre concentrations will introduce non-linear effects owing to greater absorption at the face of the crystal than in its interior; however, these effects should not seriously affect the performance of such a device.

One mode of operating such a device would involve a thin crystal, two sides of which would be silvered and approximately parallel. The silvered sides would have two small apertures, thus permitting a long path for the radiation which is to be amplified due to multiple reflexions. The pumping radiation would fall on the face of the crystal at right angles to the stimulating radiation and would traverse the crystal in its shortest dimensions.

The noise inherent in such a system would be the result of spontaneous emission within the crystal; however, this spontaneously emitted radiation would be contained in a 4π steradian solid angle and very little of it would be travelling in such a direction as to emerge from the crystal through the small exit aperture. One may most probably measure the spontaneous emission emerging from a small exit aperture. However, we believe that the stimulated emission will be much greater under operating condition and the noise should not be a major problem. Thus, the spontaneously emitted radiation will lower the density of systems in the excited state, but should not be a serious limitation from the standpoint of noise.

Dimensions of Electrical and Magnetic Quantities

FOR rather more than ten years the rationalized M.K.S. system of units has been generally accepted as the most satisfactory one to employ for practical calculations involving electrical and magnetic quantities[1,2]. This system side-steps the question of dimensions by introducing two unfortunate expressions—permittivity and permeability of free space—and assigning to them, respectively, the values $10^{-9}/36\pi$ farad/metre and $4\pi \times 10^{-7}$ henry/metre. Any dislike aroused by these terms may, however, be easily overcome by giving them new names: electric factor and magnetic factor, the question of units being left until later.

Unfortunately, the situation regarding dimensions is less satisfactory and still remains unsettled. L. H. A. Carr[3] has invoked the special theory of relativity to show that dimensionally Coulomb's law for the force F between charges q_1 and q_2 at a distance r apart in a uniform medium is $[F] = [q^2 L^{-2}]$, and from this relation all electrical and magnetic quantities can be expressed solely in the dimensions mass, length and time. Carr's proposal, however, does not seem to have been taken up and is not even mentioned in recent text-books[4,5].

An alternative suggestion is to regard q as a dimension in its own right[2]; but this settles nothing and leads to the singularly useless result that electromotive force $[E] = [ML^2 T^{-2} q^{-1}]$, implying that E is inversely proportional to q, whereas in fact the inverse is true. It is the purpose of this communication to advance evidence in support of Carr's proposal and to demonstrate that it leads to a very satisfactory direct physical relationship between electrical and magnetic quantities and their dimensions.

The gravitational force of attraction F between two masses is given by $[F] = [G M^2 L^{-2}]$, where G is the so-called gravitational constant and is necessary to make the equation balance dimensionally. However, gravitational attraction is independent of the medium and the introduction of G is quite arbitrary. Mass is only a convenient way of assessing the quantity of matter in a body, and it happens that in the gravitational equation its use leads to a rather awkward result dimensionally. An equally legitimate method for assessing a quantity of matter is to count protons or electrons, a neutron being supposed for this purpose to contribute one of each. It follows then that if two bodies are represented by $N_1 q_0$ and $N_2 q_0$, where q_0 is the elementary charge and N_1 and N_2 are pure numbers, $[F] = [q^2 L^{-2}]$ when $[M]$ in the gravitational equation is replaced by $[q]$ and $[G]$ is discarded as being unnecessary. From this it follows that $[q] = [M^{\frac{1}{2}} L^{\frac{3}{2}} T^{-1}]$, in agreement with Carr. It has been objected that dimensions with fractional exponents are meaningless, but this is merely a point of view, for if $[q]$ is taken as the fundamental quantity rather than $[M]$, then $[M] = [q^2 L^{-3} T^2]$ and the fractions disappear. Even though the relation $[q] = [M^{\frac{1}{2}} L^{\frac{3}{2}} T^{-1}]$ is not very attractive, the expression for the energy of a charged sphere, $\frac{1}{2}q^2/r$, is simple enough and the dimensions of q follow directly from this. Having established the dimensions of charge, it follows that $[E] = [M^{\frac{1}{2}} L^{\frac{1}{2}} T^{-1}]$. This relationship is equivalent to $[E] = [F]^{\frac{1}{2}}$ and is quite satisfactory since the force of attraction between two similar parallel plates, oppositely charged, can be directly measured and is found experimentally to be proportional to E^2, where E is the electromotive force between them.

The energy stored in a capacitor is $\frac{1}{2}CE^2$ and it follows therefore that $[C] = [L]$, and since E^2/R is the rate of doing work, $[R] = [L^{-1} T]$. Combining $[R]$ and $[C]$ we have $[R.C] = [T]$ and this result is independent of the nature of the medium. The identification dimensionally of RC with time is not difficult to accept when it is realized that the important criterion is that it shall be possible to measure time by means of a combination of resistance and capacitance. This is done by charging the capacitor to a convenient voltage E and connecting a resistor across its terminals. After time RC the voltage has dropped to $1/e$ of its original value, where $e = 2{\cdot}718$.

It is sometimes argued that capacitance cannot be physically equivalent to length, even though the capacitance of a sphere is proportional to its radius; but employing the criterion used for RC, namely that the dimension in question must be measurable by the quantity or quantities concerned, all that is necessary is to charge a parallel plate capacitor to a given voltage and then observe the rise in voltage as the plates are separated. The voltage is proportional to the distance apart of the plates and therefore the voltmeter used can be directly scaled to indicate distance.

Resistance also may be used to measure length in a direct manner since the resistance of a wire of constant cross-section is proportional to its length. However, resistance varies as length divided by area of cross-section, that is, $[L^{-1}]$, and in fact it is proportional to $[L^{-1} T]$, which is reasonable since for a fixed applied voltage resistance is inversely proportional to the mean velocity of electron flow. The impedance of free space (nearly 377 ohms) is obtained by multiplying the velocity of light in m./sec. by the electric factor $10^{-9}/36\pi$ and taking the reciprocal. Dimensionally this checks with $[R] = [L^{-1}\ T]$, for now, of course, the electric factor is dimensionless. The law of force between two charges in a uniform medium becomes $F = q_1\ q_2/\alpha\ r^2$, where α is proportional to the dielectric constant of the medium and is a pure numeric.

The dimensions of magnetic pole, m, are readily obtained from the relation $[m.q] = [M\ L^2\ T^{-1}]$ which is independent of the medium. From this equation, $[m] = [M^{\frac{1}{2}}\ L^{\frac{1}{2}}]$ and the law of force between two magnetic poles, m_1 and m_2, spaced a distance r apart in a uniform medium is given by $F = m_1\ m_2\ c^2/\beta r^2$, where c is the velocity of electromagnetic radiations *in vacuo* while β is proportional to the permeability of the medium and is a pure numeric. The relation $[m] = [M^{\frac{1}{2}} L^{\frac{1}{2}}]$ may not look promising but for a U-shaped magnet with poles at its extremities, the force between the poles produces a bending moment in the magnet and a very direct connexion between $[m^2]$ and $[ML]$ is apparent. The magnetic factor applicable to the rationalized M.K.S. system is proportional to β/c^2 and should therefore be given in units of sec.^{2}/m.^{2}.

The equation $[F] = [q^2\ L^{-2}]$ is the only one which leads to the plausible relationships discussed above. More general equations are $F = \dfrac{q_1\ q_2}{\alpha\ \varkappa_0\ r^2}$ and $F = \dfrac{m_1\ m_2}{\beta\ \mu_0\ r^2}$, where $\varkappa_0$ and μ_0 represent unknown properties of free space and $\varkappa_0\mu_0 = 1/c^2$. Let $\mu_0 = 1$ and $\varkappa_0 = 1/c^2$, from which we obtain $[E] = [M^{\frac{1}{2}}\ L^{\frac{3}{2}}\ T^{-2}]$, $[C] = [L^{-1}\ T^2]$ and $[R] = [LT^{-1}]$. These expressions cannot be simply related to the nature of the quantities concerned and, for example, capacitance becomes the inverse of acceleration, while resistance has the dimensions of velocity, the inverse of what might reasonably be expected.

CHEMICAL ENGINEERING

Inversion of a Laplace Transform arising from a Problem in Applied Chemical Kinetics

THE solution to a problem (Wood, T., unpublished work) arising from an analysis of a closed circuit consisting of a stirred-tank reactor and a tubular reactor in series, with first-order, isothermal, irreversible kinetics, involves finding the inverse of the Laplace transform :

$$\bar{c}(s) = \frac{1}{s + \beta_1 - \beta_2 . \exp(-\beta_3 s)}$$

where β_1, β_2, β_3 are known, positive, constants. The transform can be re-arranged:

$$\bar{c}(s) = \frac{\dfrac{1}{(s + \beta_1)}}{1 - \dfrac{\beta_2}{(s + \beta_1)} . \exp(-\beta_3 s)}$$

Since no tabulated transform could be found, the denominator was expanded as a power series, giving:

$$\bar{c}(s) = \sum_{n=0}^{\infty} \left[\frac{\beta_2{}^n}{(s + \beta_1)^{n+1}} . \exp(-n\beta_3 s)\right]$$

The inverse of the transform is now readily shown to be[1]:

$$c(t) = \sum_{n=0}^{\infty} \frac{\beta_2{}^n}{n!} . (t - n\beta_3)^n . \exp\{-\beta_1(t - n\beta_3)\} . H(t - n\beta_3)$$

where $H(t - n\beta_3) = 0$ when $t \leqslant n\beta_3$; $H(t - n\beta_3) = 1$ when $t > n\beta_3$.

The validity of the solution in this particular case was proved by its ability to satisfy the original problem and the given initial and boundary conditions. It would be of interest to know, in the general case, the conditions for which the approach adopted above is valid.

GEOLOGY

Continuation of the Great Glen Fault beyond the Moray Firth

THE Great Glen Fault was shown by W. Q. Kennedy[1] to be a sinistral tear fault on which a displacement of about 65 miles has occurred since Middle Old Red Sandstone time. E. M. Anderson[1] considered that "the curvature of the fault trace may indicate that we are dealing with the south-western sector of a major fault and that the main extension of the dislocation will probably lie to the north-east". This curvature is a gradual change of strike from about 040° in Loch Linnhe to about 035° at Inverness.

Examination of the submarine topography of the Moray Firth, Orkney and Shetland areas shows that a possible course for the Great Glen Fault lies through Shetland to the edge of the continental shelf north of Shetland[2]. The features which seem to indicate the continuation of the fault in this direction are shown in Fig. 1. Between Smiths Bank and the Caithness coast, a shallow submarine valley is especially well shown by the 30-fathom contour; the axis of this valley has a strike of 035° like the Great Glen Fault at Inverness. However, to pass along the axis of the valley, the strike of the fault north-east of Inverness has to change from 035° to 040° and then back again to 035° over a distance of about 40 miles.

To the north, the sea-floor east of Orkney is rather flat and featureless, and provides no evidence. If the fault crosses it with a gradual swing in strike towards the north, it runs into, and along, a trench to the south-west of Fair Isle shown up by the 50-fathom contour. The axis of this trench has a strike of about 025° to the south-west of Fair Isle and swings round to about 020° in its continuation up the west side of Shetland; it reaches its greatest depth of more than 70 fathoms at its northern end in a latitude of 60° N.

At the northern end of the trench, if the fault passes just east of the deepest part and to the west of The Deeps (a narrow submarine valley extending beyond the end of the trench and shown up by the 50-fathom contour) it runs ashore in Shetland at the head of Seli Voe and joins on to the Walls Boundary Fault[3]. The Walls Boundary Fault can be followed overland until it runs into the sea at Aith Voe. Still farther north it crosses the isthmus at Brae and can then be traced intermittently up the east coast of North Maven.

In the region between Seli Voe and Aith Voe, Old Red Sandstone intruded by granite lies to the west of the fault and gneisses and granite to the east. Finlay[3], and the Survey[4] report shattering, shearing and mylonitization on an extreme scale in the Old Red Sandstone and the granite, up to distances of more than a mile to the west of the fault. There is much shearing of the metamorphic rocks up to a mile to the east of the fault. At Brae, where the fault crosses the isthmus, it lies in a half-mile wide belt of intense shearing and shattering. On the east coast of North Maven, typical pegmatitic granite of the Graven Intrusive Complex of Delting[5] which is on the east side of the fault is in contact with low-grade schists and phyllites on the west side of the fault. About a mile farther west these metamorphic rocks are separated from a granite by a parallel fault. Intense shattering and shearing are associated with these faults.

The Walls Boundary Fault seems to be one of the most powerful dislocations in Shetland. No correlation across it seems possible; there is little similarity between either the metamorphic or the Old Red Sandstone rocks on either side of it. To the east, the Old Red Sandstone contains no contemporaneous or intrusive igneous material, while to the west it contains great thicknesses of volcanic ashes and lavas and is cut by a series of late granites. The Old Red Sandstones cut by the Walls Boundary Fault are considered by Finlay[3] to be of Lower Old Red Sandstone age. This indicates an age later than Lower Old Red Sandstone for a displacement of major proportions on the fault, and agrees with the findings of Kennedy for the Great Glen Fault.

North of Shetland the sea-floor is rather flat and featureless for some distance. However, the 100-fathom contour shows a small southward invagination on the strike of the projected fault if it continues its anticlockwise swing in strike (Fig. 2). To the north of the 100-fathom contour on the continental slope is a very large-scale feature of a type which would be expected if the continental slope itself had been intersected and offset by a sinistral tear fault with a displacement of about 50 miles.

CHEMISTRY

Bond-Lengths in Solid Helium

RECENTLY, Vignos and Fairbank[1] reported the existence of a new solid phase of helium-4 which exists in a narrow range of pressure between 1·45° K. and 1·78° K. They have designated the new solid as the γ-phase. Its density is less than that of the α-phase (hexagonal closest packing) of helium with which it is contiguous. It is known[2,3] that in helium-3 at a temperature almost as low, there is a phase transition in the solid from hexagonal closest packing to a less-dense phase which is body-centred cubic. Reasoning by analogy, the authors believe the new phase will be found to have the body-centred cubic, *A*2, structure.

In 1947 Pauling[4] developed an equation which has been successful for treating covalent and metallic bonds and for estimating their change in length on a change in co-ordinating number. Thus, for a proposed change in structure, one could in many cases compute the molar volume of the new structure from the cell constants of the old one. The equation is given in the form:

$$R(1) - R_n = 0{\cdot}300 \log n$$

Here $R(1)$ is the single bond-radius of the element, R_n the radius along a bond direction in a structure, and n is the bond number. Furthermore, n equals v/N, where v is the valence and N is the number of bonds.

In the hexagonal closest-packed structure, each atom has twelve nearest neighbours and in the *A*2 structure eight. Because of the fewer neighbours in the cubic structure, the bond-radii will be shorter even though the molar volume may be greater. If bonds were formed with only the nearest neighbours, the decrease in bond-radius would be:

$$\Delta R = R_n(12) - R_n(8) = 0{\cdot}300 \log 12/8 = 0{\cdot}053\,\text{Å}.$$

However, in the *A*2 structure, there are six more neighbours at a distance only slightly longer than that of the nearest eight, and therefore some of the bond-forming power of the atom is used to make bonds with them. This results in the bond-number of the shorter bonds being less than $v/8$ and the correction in bond radius becoming less than 0·053 Å. Thus in the case cited by Pauling[4], of zirconium, which undergoes a phase transition of the kind discussed here, the bond-number of the stronger bonds is near $v/9{\cdot}24$ and ΔR is observed to be 0·037 Å.

Although the bonds in solid helium are mainly van der Waals, it is nevertheless instructive to apply Pauling's equation to the known phase change in helium-3. The molar volumes of helium-3 at 2·805° K. at the hexagonal-cubic transition line as deduced from the results of Grilly and Mills[2] are 19·088 c.c. and 19·206 c.c. respectively. From this one obtains $R_n(12) = 1{\cdot}776$ Å., $R_n(8) = 1{\cdot}730$ Å., and $\Delta R = 0{\cdot}046$ Å. The observed ΔR of 0·046 Å. corresponds to a bond-number of $v/8{\cdot}43$. This value of the bond-number is larger than that observed for zirconium partly because the unit cell of helium is larger and partly because the van der Waals forces have a short range. One would not expect these forces to form proportionally as strong a bond with the six farther neighbours as would be the case with structures having covalent or metallic bonding.

Returning to helium-4, if the new phase has the cubic body-centred structure as is supposed, one can compute the change in molar volume during the solid–solid transition. Referring again to the results of Grilly and Mills[2], the molar volume of solid helium-4 under a pressure of 29·88 kgm./cm.^{2} (near 1·723° K.) is 20·742 c.c. The method used in the experimental determination indicates that this is probably the volume of the hexagonal phase (Mills, R. L., and Grilly, E. R., personal communication). In accordance with this, the bond-radius, $R_n(12)$, of 1·826 Å. is obtained. If one uses as a first approximation the correction in bond-radius of 0·046 Å. that occurs in helium-3, then $R_n(8)$ will be 1·780 Å. The latter distance gives a molar volume for the cubic phase of 20·929 c.c. and a ΔV of transition to this form of 0·187 c.c./mol.

Swenson[5] reports the molar volume of solid helium-4 at 28·06 kgm./cm.^{2} pressure (1·6° K.) to be 20·95 c.c. If this solid is also in the hexagonal form, then one obtains 0·189 c.c./mole as the ΔV of transition. If, however, the solid has the *A*2 structure, then the ΔV of transition would be higher by only 0·014 c.c./mole.

Preparations are now under way at this Laboratory to determine the crystal structure of the new solid form.

This work was carried out under the auspices of the U.S. Atomic Energy Commission.

Thermo-electric Phenomena in Electrodialysis Systems

ALTHOUGH several authors, notably Staverman[1] and Spiegler[2], have applied the methods of the thermodynamics of the steady-state to the treatment of electrodialysis processes, little or no attention has been given to the possible existence of heat fluxes in electrodialysis experiments. Of course, very useful relationships can be obtained between the flow of charge and the flow of matter through an appropriate treatment of an isothermal experiment, but we cannot say that we have described the system unless we consider the possibility of heat flows induced by these transport processes.

The argument in favour of this point of view may be roughly summarized as follows. We should like to find an expression for the rate of entropy generation, and if $\bar{S}$ is the entropy current in the steady system then:

$$\dot{S} = \nabla.\bar{S} = \frac{1}{T}\nabla.\bar{Q} + \bar{Q}.\nabla\left(\frac{1}{T}\right)$$

and by an argument based on the existence of local equilibrium within infinitesimal elements of the system:

$$\nabla.\bar{Q} = -\Sigma_i\nabla\mu_j.\bar{J}_j$$

where μ's are the total potentials (chemical, electrical, etc.) and the $\bar{J}$'s are currents of matter or electricity. A more complete discussion of this line of reasoning has been given by Callen[3]. In writing out a complete expression for the various currents that may exist in an electrodialysis system we must deal in the simplest case with at least four items: salt flow, solvent flow, electric current and a heat current. In an electrochemical system, it is convenient to formulate these flows in terms of the ions, the solvent and the heat. The electric current is, of course, the sum of individual ionic flows multiplied by the appropriate ionic charges.

Flow of positive ions $\Phi_1 = -L_{11}\frac{1}{T}\nabla\mu_1 - L_{12}\frac{1}{T}\nabla\mu_2 - L_{13}\frac{1}{T}\nabla\mu_3 + L_{14}\nabla\left(\frac{1}{T}\right)$

Flow of negative ions $\Phi_2 = -L_{21}\frac{1}{T}\nabla\mu_1 - \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad + L_{24}\nabla\left(\frac{1}{T}\right)$

Flow of solvent $\Phi_3 = -L_{31}\frac{1}{T}\nabla\mu_1 - \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad + L_{34}\nabla\left(\frac{1}{T}\right)$

Flow of heat $\Phi_4 = -L_{41}\frac{1}{T}\nabla\mu_1 - L_{42}\frac{1}{T}\nabla\mu_2 - L_{43}\frac{1}{T}\nabla\mu_3 + L_{44}\nabla\left(\frac{1}{T}\right)$

Elimination of all terms in ∇T simplifies the situation but clearly does not guarantee that $\Phi_4 = 0$.

I have begun a study of the coupling between the electrical currents and the possible heat flows in electrodialysis systems using the apparatus indicated schematically in Figs. 1 and 2. In the first experiments, made with the apparatus shown in Fig. 1, measurement of the voltage developed between the isothermal probes showed that an electrical current did indeed flow under the influence of a temperature gradient, and the sign of the potential indicated that, contrary to my initial expectation, the salt was becoming concentrated in the warmer part of the loop. Unfortunately, this particular apparatus is not suitable for obtaining quantitative relationships with thin-film ion exchange membranes.

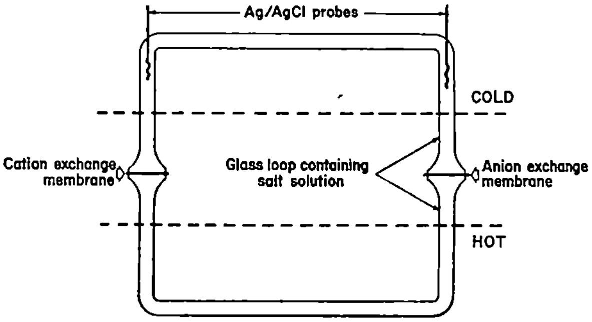

Fig. 1. Apparatus used to demonstrate coupling between heat flow and current flow in dialysis system. Salts tested, 1 *N* sodium chloride and 1 *N* lithium chloride. Left electrode is invariably negative when temperature is controlled as shown

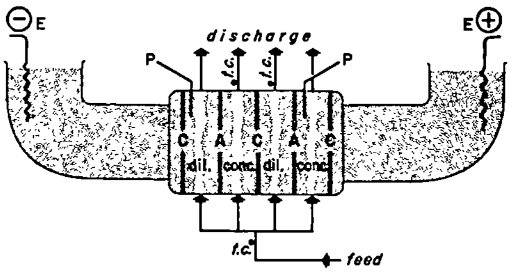

Fig. 2. Apparatus used to measure heat flow between diluting and concentrating compartments. *P*, Probes; *C*, cation exchange membrane; *A*, anion exchange membrane; *E*, power electrode (heavy silver/silver chloride mesh); *t.c.* ●, thermocouple

Some quantitative results have, however, now been obtained with the apparatus indicated schematically in Fig. 2. Electrodialysis experiments have been conducted in this system under adiabatic conditions. The liquid circulation-rates through the various compartments are made as nearly equal as possible; and, with the electric current and the circulation-rate adjusted so that there is little or no change in the concentration of the fluid as it passes through the alternating diluting and concentrating compartments, the changes in temperature in the streams indicated are measured. An estimate of the I^2R heating per cell is obtained from the current passed and the voltage developed at the probes. Under the conditions of these experiments, this loss is equally distributed between the cells; and, from this, the flow-rates, and the observed differences in the rise in temperature, we can calculate the amount of heat transferred into or out of a compartment due to transfer of salt across the membranes. The following preliminary results have been obtained:

Salt	Temperature rise Concentrated stream	 Diluted stream	Heat transferred per faraday
1 *M* Sodium chloride	0·275° C.	0·65° C.	3,030 cal.
1·27 *M* Lithium bromide	0·30° C.	0·50° C.	2,930 cal.
1·27 *M* Lithium bromide	0·10° C.	0·30° C.	3,240 cal.
8·4 *M* Lithium bromide	1·05° C.	1·70° C.	3,420 cal.
8·4 *M* Lithium bromide	1·38° C.	2·30° C.	3,510 cal.

These results are in rough agreement with those that can be calculated more directly from the fluid circulation-rates and the estimated heat capacities of the solutions used. In every case, flow of heat across the membrane is in a direction opposite to the flow of matter. I do not believe that these very substantial heat quantities are due to the existence of terms such as $-T\Delta S\nabla\left(\frac{1}{T}\right)$ (this term results from $\frac{1}{T}\frac{\partial\mu}{\partial T}\nabla T$ in the full expression for $\nabla\mu$) in the formulation that I have used to describe the currents of matter, electricity and heat, because, as has been shown by deBethune[4], the appropriate ΔS here is only of the order of a few cal./mole and in any event in the experiments I have performed $\nabla\left(\frac{1}{T}\right)$ is a very small quantity. The heat effect appearing here must be regarded as the electrochemical analogue of the Peltier effect.

Further work on a more refined apparatus in which we can further minimize thermal gradients is in progress, and a more complete report on the results is planned.

Crystal and Molecular Structure of Diphenyl

X-RAY diffraction studies of crystalline diphenyl have been described by a number of authors[1-4] but the bond-distances and bond-angles have not been determined as accurately as in other aromatic compounds recently reported[5]. A detailed X-ray investigation of this structure has now been completed, and in view of the relevance of accurate structural information to modern valency theory, some results of this analysis are reported here.

Three-dimensional counter diffractometer data within the range $0 < \frac{\sin\theta}{\lambda} < 0.61$ have been refined by the method of least squares. The average estimated standard deviations:

$$\sigma_{xi} = [C_{ii}^{-1}\Sigma\omega\Delta^2/n - k]^{1/2}$$

(where C_{ii}^{-1} is the appropriate diagonal element of the inverse of the 9×9 matrix solved for each atom[6]) are 0·0016 Å. and 0·019 Å. for carbon and hydrogen co-ordinates respectively. The usual residual factor for 540 observed reflexions is 0·038; the space group is shown conclusively to be $P2_1/c$ and the molecule is therefore centrosymmetric and cannot be twisted as it is in the vapour phase[7].

The molecule is not strictly planar; the equation of the least-squares plane through the asymmetric unit[8] is:

$$-0·30584\,X + 0·55575\,Y + 0·77305\,Z' = 0·10114$$

while that of the mean molecular plane is:

$$-0·30891\,X + 0·55579\,Y + 0·77810\,Z' = 0$$

(These direction cosines refer to the orthogonal crystal axes a,b,c'.) The root mean square deviations from the ring plane are 0·0035 Å. for carbon atoms (maximum = 0·0049 Å.) and 0·012 Å. for hydrogen atoms (maximum = 0·017 Å.). The observed deviations of the carbons from this plane, while small, are statistically significant ($\chi^2 = 29·1$ with 3 degrees of freedom)[9] and are possibly due to intermolecular packing. For the molecular plane, the root mean square deviations are 0·0050 Å. and 0·019 Å. ($\chi^2 = 58·3$ with 4 degrees of freedom).

The bond-distances and -angles derived directly from the best least-squares co-ordinates are given with their estimated standard deviations in Fig. 1. These values require correction for the effects of molecular rigid body librations, and analysis[10] of the thermal vibration parameters in terms of such modes leads to the corrected distances, angles and estimated standard deviations given in Fig. 2. The effect of this correction is to increase all the carbon–carbon bond distances and to make all bond-angles more nearly equal to 120°. The deviation of the angles *BAF* (~ 17σ) and *ABC* (~ 10σ) from this value are, however, still highly significant. The difference (~ 8σ) between the distances *AB* and *CD* is also significant, and the differences *AB–BC* and *BC–CD* are just at the significance-level.

Since there are no significant differences between any two chemically identical but crystallographically non-equivalent distances or angles it seems unlikely that the estimated standard deviations are seriously under-estimated. In addition, since the least-squares results indicate no significant displacements of the ortho-hydrogens from a planar trigonal arrangement it appears that hydrogen–hydrogen repulsive interactions, to which the apparent non-planarity of the molecule in the vapour phase[7] has been attributed, cannot seriously affect bond-distances or bond-angles which involve only carbon atoms[14]. The observed deviations of the intra-ring carbon atoms from a regular hexagonal arrangement and the 0·20 Å. perpendicular separation between the planes of the two phenyl rings are probably due to intermolecular crystal forces. The effects of π electron delocalization across the linking bond should be small and, moreover, should increase the intra-ring bond-distances above the benzene value (1·397 Å.) whereas the observed values of *CD* and *BC* are shorter than this.

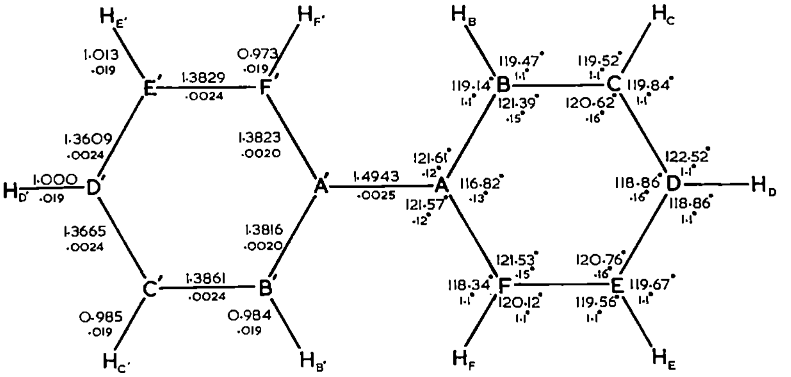

Fig. 1. Bond-distances and -angles uncorrected for libration

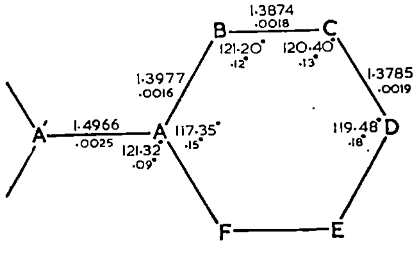

Fig. 2. Bond-distances and -angles corrected for libration

The intra-ring bond-distance is of considerable interest in relation to the recent discussion[11-15] on the effect of hybridization on carbon–carbon distances. The π bond-order derived from simple molecular orbital calculations is 0·37 (ref. 16), and more sophisticated self-consistent field calculations, such as have been reported for butadiene[12], indicate that the correct value is probably considerably less than this. The shortening due to double bonding must therefore be small and the observed distance of 1·497 Å. cannot differ greatly from that of a $C(sp^2) - C(sp^2)$ 'single' bond. This distance is significantly greater than 1·48 Å., which has been suggested[13] for the $C(sp^2) - C(sp^2)$ single bond distance. It is, however, consistent with the proposed distance of 1·51 Å. if, as has been suggested[17], the variation of bond-distance with bond-order is less rapid at low bond-orders than in other regions of the order-distance curve.

The calculations involved in this investigation were carried out on the University of London *Mercury* computer. I am indebted to Mr. O. S. Mills and Drs. J. S. Rollett and R. A. Sparks for making available their programmes for crystallographic calculations.

I am also indebted to Prof. C. J. B. Clews both for suggesting this problem and for his continual encouragement; to Prof. D. P. Craig and Drs. R. Mason and P. Pauling for much helpful discussion; and to the University of Western Australia for providing a research grant.

Pyrene Dimers

THE striking change in the fluorescence spectrum from pyrene in benzene as a function of the pyrene concentration was studied by Förster and Kasper[1]. They concluded that the violet emission is produced by monomolecular pyrene while the blue emission is from transient dimers. Schmillen[2] has observed similar changes in the fluorescence spectrum from pyrene in solid hydrocarbons and has reported decay times of 8·9–9·9 nsec. for monomolecular pyrene and approximately 89 nsec. for pyrene complexes. The true value of the lifetime of pyrene dimers in liquid solutions has recently been the subject of discussion[3,4]. This communication reports the results of studies of changes in the fluorescence lifetime and in the emission spectrum of pyrene in paraxylene and in cyclohexane for various concentrations of pyrene.

Paraxylene and cyclohexane were purified with two vacuum distillations, but the pyrene (which, like the solvents, was obtained from the Eastman Kodak Co.) was used without further purification. The sample solutions were flushed with nitrogen before each measurement to obviate oxygen quenching and were handled with caution since pyrene is listed[5] as a carcinogen.

Decay times were measured using apparatus[6] which produced a pulsed beam of electrons of 75 keV. energy to excite the fluorescence, and a 1*P*28 photomultiplier and associated equipment for detecting, and graphically recording, the shape of the emitted light pulse. Each component in the fluorescence emission was studied by interposing either a 9863 Corning filter or a Wratten 2 series VI filter to pass the violet and blue components, respectively. This equipment can measure decay times conveniently over a range of 2–200 nsec. Longer components in the decay could be observed but not accurately determined.

Table 1. MEASURED DECAY TIMES

Solute	Solute concentration (gm./l.)	Filter type	Decay time (nsec.)
—	Pyrene crystals	Wratten 2 (blue)	91 ± 5
Xylene	0·1	Wratten 2 (blue)	91 ± 10
Xylene	0·5	Wratten 2 (blue)	91 ± 10
Cyclohexane	0·5	Wratten 2 (blue)	81 ± 10
Xylene	0·1	9863 (violet)	91 ± 5
Xylene	0·5	9863 (violet)	70 ± 4
Cyclohexane	0·5	9863 (violet)	65 ± 4

The measured decay times for several sample solutions are listed in Table 1. The two arbitrary values of the concentration of pyrene in xylene, 0·1 and 0·5 gm./litre, are chosen because with the former concentration the blue component in the emission spectrum is starting to assume its characteristic shape whereas, in the latter case, the blue component is quite prominent. No decay-time data are reported for a 0·1 gm./litre pyrene–cyclohexane solution as the fluorescence yield is too small to be measured accurately.

It is noted in Table 1 that the value for the violet component is, to a small extent, dependent on the solute concentration. The decrease in the decay time of the violet component with increasing solute concentrations coincides with the decrease in the intensity of the emission yield. For the same concentration (0·5 gm./l.) of pyrene, the value of the decay time and emission intensity of the violet component is less when the solvent is cyclohexane rather than xylene. These observations are consistent with one of two mechanisms which can explain the formation of the anomalous blue component at the expense of the violet component: (1), the existence of transient dimers or (2), energy transfer from monomeric pyrene to permanent aggregations.

Moreover, it was observed that the time taken for the blue component to rise is at least an order of magnitude longer than that of the violet component, and that it becomes shorter with increasing solute concentration. Since a long time in rising is indicative of a delay in the emission process, this observation supplies further evidence for either of the two postulates.

Fluorescence spectral measurements[6] were made to compute the energy-transfer parameter ε in an attempt to ascertain the existence and proliferation of permanent aggregations. A thin (0·05 mm.) sample of solution was excited with 265-mμ radiation from a Bausch and Lomb monochromator and the transmitted emission spectra from both solvent and solute were recorded by a Beckman *DK*-2 spectrophotometer. The exciting light is almost completely absorbed by the solvent. Some of this excitation energy is re-emitted and a portion is transferred to solute molecules. From the change in the intensity of the solvent yield the value of ε could be determined[6] and over the concentration range of 0·05–2 gm./l., ε, as a fraction of unity, could be expressed to a good approximation by the relationship $\varepsilon = 6{\cdot}8c/(1 + 6{\cdot}8c)$, where c is the solute concentration in gm./l. If, following Cohen and Weinreb[7], one interprets a linear dependence of c/ε versus c as an indication that only one level in the solvent molecule and only one species of acceptor molecule are active in the energy-transfer process, one must conclude that if there were permanent aggregations of pyrene they do not noticeably contribute to the deactivation of the excited solvent molecules.

Although these results provide supporting evidence for the assumption of transient dimers as postulated by Förster and Kasper[1], they are not sufficiently conclusive to eliminate other interpretations.

2,6-Difluoropyridine

As part of a programme involving the investigation of general laboratory methods for the preparation of fluoropyridines[1], we wish to report the synthesis of 2,6-difluoropyridine. The only other recorded example of a pyridine containing more than one nuclear fluorine is pentafluoropyridine[2,3], which was prepared by methods best suited for the synthesis of perfluoro-aromatic compounds.

The present report describes the synthesis of 2,6-difluoropyridine from starting materials readily obtainable by standard laboratory procedures. Conversion of methyl 6-fluoropicolinate[4] (60·0 gm.) to 6-fluoropicolinic hydrazido (51·2 gm.), m.p. 120·5–121° (found: C, 46·7; H, 4·0; $C_6H_6FN_3O$ requires C, 46·5; H, 3·9 per cent), with hydrazine in methanol, followed by a modified Curtius-type degradation, gave 2-amino-6-fluoropyridine, m.p. 58–59° (found: C, 53·6; H, 4·3; N, 24·9; $C_5H_5FN_2$ requires C, 53·6; H, 4·5; N, 25·0). As it is known that fluorine atoms adjacent to aromatic ring nitrogens undergo facile hydrolysis in acid solution[5], it was found advisable to reverse the normal addition procedure of the Curtius degradation. Consequently, addition of *N* hydrochloric acid to a stirred slurry of sodium nitrite dissolved in water, 6-fluoropicolinic hydrazide (20·0 gm.), and ether gave 6-fluoropicolinic azide. This was decomposed in warm carbon tetrachloride to crude 6-fluoropicolinic *iso*cyanate, which was hydrolysed directly to 2-amino-6-fluoropyridine (7·2 gm.) with 50 per cent aqueous acetic acid. By use of Roe's modification of the Schiemann reaction[6], 2-amino-6-fluoropyridine (10·0 gm.) was converted to 2,6-difluoropyridine (2·8 gm.), b.p. 124·5° (743 mm.), n_D^{25} 1·4349 (found: C, 52·2; H, 2·6; N, 12·1; $C_5H_3F_2N$ requires C, 52·2; H, 2·6; N, 12·2).

The infra-red spectrum of 2,6-difluoropyridine in carbon tetrachloride, obtained with a Perkin–Elmer model 21 spectrophometer equipped with sodium chloride optics, showed absorptions at 1,607, 1,592 and 1,493 cm.$^{-1}$, providing evidence for a pyridine nucleus. Additional absorptions at 3,110 and 717 cm.$^{-1}$ contribute support for the proposed structure of this compound.

2,6-Difluoropyridine is exceptionally volatile and shows the same solubility characteristics as 2-fluoropyridine. In contrast to pentafluoropyridine, it does exhibit some basic properties in 50 per cent ethanol when titrated against 0·01 *N* hydrochloric acid. However, no hydrochloride was formed in ethereal hydrogen chloride and no picrate formed in ethanol.

An attempt to prepare 2,3-difluoropyridine from methyl 2-fluoronicotinate (10·0 gm.), b.p. 101° (10 mm.), n_D^{25} 1·4978 (found: C, 54·4; H, 3·9; N, 9·1; $C_7H_6FNO_2$ requires C, 54·2; H, 3·9; N, 9·0) by a similar route failed because hydrazine was found to react preferentially with the fluorine rather than the ester moiety giving methyl 2-hydrazinonicotinate (1·3 gm.), m.p. 106–106·5° (found: C, 50·4; H, 5·4; N, 25·4; $C_7H_9N_3O_2$ requires C, 50·3; H, 5·4; N, 25·1).

A more detailed report of this and related work will be published elsewhere.

RADIATION CHEMISTRY

Polarization induced by Radiation in 'Perspex'

IF, after irradiation of a thick piece of 'Perspex' with a sufficient number of electrons of a few MeV., the specimen is knocked with a sharp tool, a rather intense 'lightning flash' is seen and a tree-like crack pattern occurs. The foot of the stem is situated at the point which was struck. Sometimes the discharge occurs spontaneously towards any disturbance at the surface of the 'Perspex' block.

As the irradiated sample is thicker than the range of the electrons, it is clear that these electrons are stopped in the 'Perspex', mainly at depths corresponding to the more or less straight sloping part of the absorption curve. The 'Perspex' being a good insulator, negative space charge builds up in the sample, and when the dose of radiation is sufficiently high, a discharge can occur.

Gross[1] has already studied this phenomenon in some detail, but some of his statements do not agree with my observations. However, I wish only to report here on another property of the irradiated specimen.

I have bombarded several identical polished 'Perspex' blocks 13 mm. × 38 mm. × 47 mm. with $1{\cdot}2 \times 10^{14}$ electrons of 2·5 MeV. The current of the linear accelerator was held at 0·1 μamp. The beam entered the blocks in the middle of one of the largest faces. The blocks were examined with a polariscope with convergent light, the specimen being placed so that one of the largest faces was viewed. Before irradiation, no interference pattern was observed. Immediately after irradiation, an interference pattern could be seen that behaved as if the 'Perspex' block was a uniaxial double refractive crystal, the optical axis coinciding with the direction of the beam. One could observe a circular isochromate and the well-known dark cross, each line of which corresponds to the direction of the polarizer and analyser. This picture disappeared very quickly at first, but more slowly later on. After an hour, it was scarcely visible and after two hours it had disappeared completely, although it was still possible to create some cracking by knocking the sample. If the specimen was knocked when the interference pattern was still strong, the pattern disappeared nearly completely. From this we may conclude that in the circumstances considered the optical properties of the 'Perspex' bombarded with electrons is mainly due to an electrical effect, the remaining part being due probably to mechanical strain caused by the non-homogeneous increase of the temperature. It seems evident that something like the Kerr electro-optic effect is occurring. The charges in the 'Perspex' are more or less situated in planes perpendicular to the original direction of the beam, causing an electric field in that direction and giving the 'Perspex' the property of behaving as a uniaxial crystal with its axis along the electric field.

BIOCHEMISTRY

Hexosamine and Sialic Acid Contents in Cells

Few data are available on the determination of glycoproteins containing sialic acid in tumour tissues, although the presence of an acid mucopolysaccharide in some kinds of tumour tissue has been reported. We determined the hexosamine and sialic acid contents in tumour cells, the HeLa cells and *C3H* ascitic hepatoma cells of different types, comparing them with those of non-malignant cells. The liver cells of *C3H* mice, and *FL* cells obtained by a tissue culture were used as non-malignant cells. The liver cell is generally considered to be a good example of the basic cell type. The types of the *C3H* ascitic hepatoma used were *MH* 134, *MH* 129 *P* and *MH* 129 *F*[1], which were inoculated into (*C3H*/*HeN*dd) F_1 hybrid mice, subcutaneously or intraperitoneally. The cells from solid tissue were prepared by use of a tissue presser. The cells were dried with acetone after washing with saline solution. The results of the determination are summarized in Table 1.

The sample used for the sialic acid determination was examined, and the absorption spectrum of the coloured solution which was produced by the resorcinol reagent was read; two peaks of absorption, with maxima at 450 and 580 mμ were obtained. This coincides with the results for sialic acid reported by Svennerholm[4]. From these results no significant difference in hexosamine and sialic acid contents was found between tumour cells and non-malignant cells. Prodi[5] reported the hexosamine contents of liver in rat, rabbit and guinea pig presenting values of 436, 408 and 405 γ/100 mgm. of dry weight. These results are only a little higher than the values obtained in *C3H* mouse liver. Hexosamine and sialic acid contents of the intact liver cells of the mice with intraperitoneally inoculated tumours were almost equal to the normal values, although the serum-level of sialic acid in mice with the same tumour was remarkably high[6]. Thus it was found that glycoprotein containing sialic acid is not stored in tumour cells as well as in the liver cells of tumour-bearing animals, even if the liver were a site of synthesis of these glycoproteins[7]. Furthermore, it may be concluded that tissue destruction is not a direct origin of the increase of serum glycoproteins in tumour-bearing subjects. The presence of a certain kind of substance which stimulates the production of sialic acid-containing substances in tumour-bearing animals is assumed. This assumption is partly based on the finding of the excretion of so-called 'κ-mucopolypeptide', which was stated to be a tumour-specific urinary mucopolypeptide[8].

Table 1. Sialic Acid and Hexosamine Contents of Cells

	Nitrogen	Hexosamine		Sialic acid	
	mgm./ 100 mgm. dry weight	mgm./ 100 mgm. dry weight	μgm./ mgm. nitrogen	mgm./ 100 mgm. dry weight	μgm./ mgm. nitrogen
FL cell	10·8	0·41	38	0·36	33
HeLa cell	12·0	0·37	31	0·46	38
Tumour cell					
MH 134 (i.p.)	12·9	0·48	37	0·26	20
MH 134 (s.c.)	14·4	0·42	29	0·36	25
MH 129*F* (i.p.)	14·1	0·40	28	0·36	26
MH 129*P* (i.p.)	14·2	0·36	25	0·32	23
Liver cell of *C3H* mice					
Normal	11·8	0·32	27	0·31	26
MH 129*F* bearing	12·6	0·33	26	0·33	26
MH 129*P* bearing	13·0	0·39	30	0·33	25

i.p., Intraperitoneally inoculated tumour; s.c., subcutaneously inoculated tumour.

Hexosamine was determined according to Boas (ref. 2), and sialic acid according to Svennerholm (ref. 3) using the orcinol reagent.

Polarographic Examination of Sialic Acids

We have investigated systematically the polarographic wave of neuraminic acid derivatives with a dropping-mercury electrode ($m = 2 \cdot 86$ mgm./sec., $t = 2 \cdot 98$ sec.). The existence of a sialic acid wave was anticipated from the fact that structurally related substances such as pyruvic acid[1,2] and fructose[3,4] give well-defined polarographic waves. Three type of waves could be observed in N-acetylneuraminic acid solution (NANA): (*a*) a hydrogen wave in 0·1 *M* LiCl or in 0·01–0·1 *M* tetramethylammonium bromide (TMABr) under *p*H 7. The apparent half-wave potential is − 1·65 V. (s.c.e.) in 0·1 *M* TMABr and − 1·48 V. in 0·01 *M* TMABr. There is a linear relationship between the height of the wave and the square root of the height of the mercury column up to 45 cm.; and, under defined conditions,

Table 1. CHARACTERISTICS OF THE WAVES OBSERVED IN NANA SOLUTIONS AS COMPARED WITH THE WAVES OF PYRUVIC ACID AND OF FRUCTOSE

Substance	Condition or pre-treatment	30° C. Half-wave potential, V.	30° C. Height μamp./μmole	60° C. Height μamp./μmole	$\frac{h60°}{h30°}$	Per cent/ degree*
Pyruvic acid	TMAOH 0·01 *M*	−1·80	77·6	91·4	1·29	0·59
Fructose	LiCl 0·1 *M*	−1·90	21·0	61·5	2·93	6·4
Fructose	TMAOH 0·01 *M*	−1·95	25·0	66·5	2·65	5·5
NANA	TMAOH 0·01	−1·96	18·3	81·8	4·47	11·6
NANA	Heated 10 min. in TMAOH 0·01 *M*	−1·65				
		−1·95	53·8	74·3	1·38	1·27
NANA	Kept frozen freshly thawed	−1·87	33·0			
NANA	Same sample kept 1 hr. at room temp.	−1·82	26·0			
NANA	Same sample kept 2 hr. at room temp.	−1·86	10·0			

* Temperature coefficient of the wave in per cent change per degree, relative to the wave at 30° C.

a linear relationship between NANA concentration and the height of the wave. Under identical conditions, pyruvic acid ($4·05 \times 10^{-4}$ *M* in 0·01 *M* TMABr, under nitrogen) gives a hydrogen wave of the same height (36·7 μamp.) as NANA (39 μamp.). The slope of the straight line in which the height of the wave is plotted as the function of concentration of NANA is 0·3 μamp./μgm./ml. or 92·7 μamp./μmole/ml. (at 30° C. in 0·01 *M* TMABr). There is a marked sensitivity of the wave to ionic strength and also to the presence of oxygen.

(*b*) When a 0·4 μmole/ml. solution of NANA in 10 μmole/ml. of TMABr is neutralized by stepwise addition of 0·01 *M* TMA-phosphate buffer at *p*H 7, the hydrogen wave decreases and another wave appears on top of it and increases as the *p*H gets closer to neutrality. This second wave has an approximate half-wave potential of −1·75 V. This stepwise change of the two waves is shown by Fig. 1 (polarograms 7, 8, 9). This second wave, given apparently by the anion of NANA, was found in 0·01 *M* tetramethylammonium hydroxide (TMAOH), *p*H 10 (Fig. 1, polarogram 1). The apparent half-wave potential of this wave is independent of the mercury pressure and has a high-temperature coefficient (Table 1). It seems to be a wave controlled kinetically.

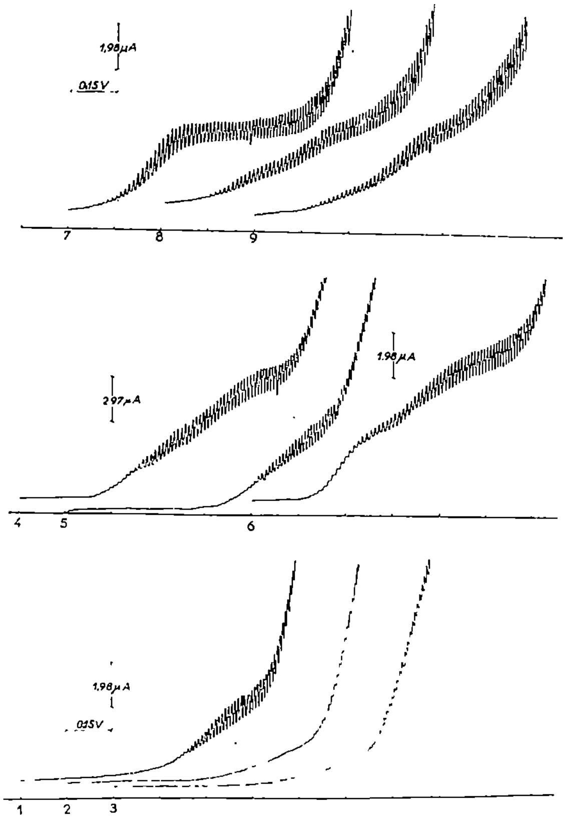

Fig. 1. Polarograms of NANA and related substances. (1) freshly thawed NANA, 1·62 μmole/ml. in TMAOH 0·01 *M* ; (2) same as (1) after 2 hr. at room temperature (24° C.) ; (3) same as (1), after 3·5 hr. at room temperature ; (4) pyruvic acid 1·60 μmole/ml. in TMAOH 0·01 *M* ; (5) fructose 1·60 μmole/ml. in TMAOH 0·01 *M* ; (6) NANA 1·60 μmole/ml. heated 10 min. in TMAOH 0·01 *M* recorded in the same solvent ; (7) NANA 0·4 μmole/ml. in TMABr 0·01 *M* (hydrogen wave) ; (8) Same as (7) after addition of 0·01 *M* $TMAPO_4$, *p*H 7, 0·6 μ*M* ; (9) same as (7) with 1·11 μ*M* $TMAPO_4$ buffer, all polarograms recorded at 30° C.

An interesting and as yet unexplained variation of the height of this wave was observed, which depended on the previous treatment of the NANA solution. Solutions adjusted to *p*H 4·5 (*p*H of maximum stability[6]) were kept frozen for several days. Freshly thawed solutions gave a higher wave than solutions kept at 4° C., or freshly thawed solutions allowed to remain for various periods of time at room temperature. The height of the wave decreased with time at room temperature. The phenomenon is apparently reversible within limits, since re-freezing and re-thawing of the material two or three times yielded in each case a wave of the same height as the originally frozen NANA solution. No carboxypyrol-derivatives could be detected by paper chromatography in frozen stored solutions, though small quantities were present in solutions kept at 4° C.

No definite statement can be made as to the nature of the reaction determining the wave-height. A ring-opening, as is the case with glucose or fructose[7], or a dehydration as shown for formaldehyde[8] may be the rate-controlling mechanism for this NANA wave.

(*c*) In heated NANA solutions (10 min. at 100° C. in 0·01 *M* TMAOH solution) a different type of wave was observed, which bears some relationship to the pyruvic acid wave (Fig. 1, polarogram 6). However, no pyruvic acid could be detected on chromatograms and the addition of lactic acid dehydrogenase and reduced diphosphopyridine nucleotide (0·005 *M*) to this solution produced a change in optical density at 340 mμ corresponding to only 10 per cent of the amount of pyruvic acid needed to account for the observed polarographic wave. No 2-carboxypyrol could be detected by paper chromatography in the heated solution. The height of the wave observed in heated NANA solutions is independent of the mercury pressure, but has a low-temperature coefficient (Table 1). Pyruvic acid in 0·01 *M* TMAOH gives a wave which decreases linearly with the square root of the mercury pressure.

More experiments are needed before any analytical application of this polarographic wave can be recommended.

The NANA was prepared from meconium according to the method of Zilliken *et al.*, and kindly provided by Dr. R. J. Winzler. Another sample re-crystallized three times was a gift from Dr. Saul Roseman, University of Michigan.

The work was supported by a grant from the National Institutes of Health (*E* 2183).

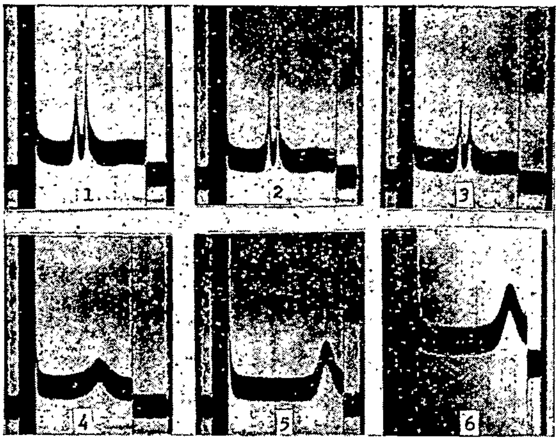
Sub-unit of Ribosomal Ribonucleic Acid from Yeast

RIBONUCLEIC acid (RNA) isolated by the phenol method from 80*s* ribosomes of yeast was demonstrated to contain two components of 19*s* and 28*s* [1]. In a previous paper[2], it was shown that by heat treatment the high molecular ribosomal RNA could easily be converted to a low molecular RNA with the sedimentation coefficient of about 4*s*. It is also the case for rat liver ribosomal RNA as demonstrated by Takanami[3]. The close agreement of the *s*-value of this heat-treated ribosomal RNA with that of soluble RNA led us to suppose that the 4*s* polynucleotide is the basic unit of all RNA's[2]. In the present work, it has been shown that trypsin, as in the case of heat treatment, can degrade ribosomal RNA into 4*s* sub-units.

Ribosomal RNA used was isolated by the phenol method from *Saccharomyces cerevisiae*, strain Kaneka. In the first series of experiments, the RNA was heated in 0·2 *M* sodium chloride for 10, 20, 40 and 60 min. at 90° C. The heated RNA solutions were observed in a Spinco *E* analytical ultracentrifuge with a schlieren optical technique at once or after dialysis against 0·1 *M* sodium chloride containing 0·01 *M* potassium phosphate buffer at *p*H 7·1. Heating for 10 min. caused a partial degradation of the RNA, giving rather continuously distributed products in the range 4*s*–13*s*, though a component of around 7*s* predominated (Fig. 4). The complete conversion to a 4*s* sub-unit ($S^0_{20} = 4 \cdot 3s$) was achieved by 40 min. heat treatment. Further heating up to 60 min. did not change the sedimentation pattern (Fig. 5).

Next, ribosomal RNA (0·5–1·0 per cent solution in 0·1 *M* sodium chloride–0·01 *M* potassium phosphate) was treated with three kinds of proteolytic enzymes respectively (all 0·15 mgm./ml.), that is, trypsin and chymotrypsin (Worthington Biochemical, United States, 2 × cryst.), chymotrypsin and pepsin (Nutritional Biochemical, United States, 2 × cryst.). The sedimentation analyses were directly made for the digest inclusive of added enzyme. The only effective enzyme in degrading the RNA was trypsin. Brief treatment of the RNA solution (20 min. at 25° C., *p*H 7·1) with this enzyme yielded polydisperse boundaries just as seen in the case of the short heat treatment. Treatment for 60–90 min., however, gave a single boundary of about 4*s* ($S^0_{20} = 4 \cdot 0s$) (Fig. 6), the sedimentation pattern being comparable with that of the 'stable sub-unit RNA' obtained by 60-min. heat treatment. Incubation for up to 90 min. at 25° C. at *p*H 7·1 without added enzyme (Fig. 1), or with chymotrypsin (Fig. 2), or incubation for 20 min. at 25° C. at *p*H 3·0 with pepsin (Fig. 3) did not affect the initial sedimentation pattern very much.



Figs. 1–6. Sedimentation patterns of yeast ribosomal RNA treated with heat or proteolytic enzymes (0·15 mgm./ml.). 1 per cent solutions in 0·1 *M* sodium chloride, 0·01 *M* potassium phosphate, *p*H 7·1. Sedimentation proceeds from right to left. Pictures taken about 30 min. after reaching 59,780 rev./min. (1) Untreated; (2) treated with chymotrypsin for 90 min.; (3) with pepsin for 20 min.; (4) heated for 10 min.; (5) heated for 60 min.; (6) treated with trypsin for 90 min.

A possibility that a trace of ribonuclease present in the trypsin preparation might be responsible for the observed effect of trypsin is probably excluded by the following tests using pancreatic ribonuclease (the action of ribonuclease having specificity different from pancreatic ribonuclease is still open to question, however). The RNA was incubated at 25° C. for 90 min. with a series of concentration of pancreatic ribonuclease (Worthington Biochemical, United States, cryst.) (0·001–1·0 μgm./ml.) and of trypsin (0·02–0·5 mgm./ml.), and the *s*-value of the main peak was recorded in relation to the concentration of the enzyme used (Table 1). In the case of ribonuclease, the higher the concentration of the added enzyme, the greater was the extent of the RNA degradation, no ultracentrifugally detectable 'end point' of

Ribosomal RNA (1 per cent solution in 0·1 *M* sodium chloride, 0·01 *M* potassium phosphate, *p*H 7·1) was incubated with the enzymes for 90 min. at 25° C.

degradation being attained. On the other hand, degradation by trypsin clearly revealed a limitation; 0·15 mgm./ml. of trypsin was sufficient to degrade RNA into 4*s*, and no further change in *s*-value was observed with increasing concentration of trypsin.

An attractive hypothesis from the above results might be that the high molecular ribosomal RNA is composed of relatively stable 4*s* sub-units which are linked together through some peptide-like substance. Acid hydrolysates of the RNA preparation (6 *N* hydrochloric acid, 120° C., 8–24 hr.) were found to give ten amino-acids after two-dimensional paper chromatography or starch column chromatography which have been identified as glycine, glutamic acid, serine, alanine, aspartic acid, amino-butyric acid, lysine, threonine, leucine and valine (roughly decreasing in amount as found). Although the fact that the RNA contains a basic amino-acid, lysine, and no aromatic amino-acid is apparently compatible with the findings that the RNA is susceptible to trypsin, but neither to chymotrypsin nor to pepsin, the amount of lysine detected was too small to account for the number of lysine residue required for the sub-unit linkage. The effect of trypsin on the ribosomal RNA presented in this communication might be related to the degradative action of some non-enzymic proteins on the high molecular RNA from Ehrlich ascites tumour cells recently reported by Brown *et al.*[4].

Quantitative Determination of Metadrenaline and Normetadrenaline in Normal Human Urine

SEVERAL authors have performed investigations on metadrenaline and normetadrenaline, metabolites of catecholamines, since their discovery by Axelrod[1]. Previous work, however, dealt mostly with the urine of rats[2], in which relatively large amounts of the metabolites are excreted, or the isotope tracer of authentic methoxycatecholamines[3] which can be detected easily by their radioactivity. Metadrenaline and normetadrenaline in normal human urine have never been determined quantitatively, because of their very low concentrations. This communication concerns the method of determination of methoxycatecholamines in urine of normal human beings.

An aliquot (5–10 ml.) of urine is adjusted to *p*H 1·0 with hydrochloric acid, and hydrolysed in a boiling water bath for 1 hr. After cooling in tap water, the urine is adjusted to *p*H 10·0 with sodium hydroxide, saturated with sodium chloride, and extracted with five volumes of ethyl acetate under vigorous shaking for 5 min. After centrifugation, the organic phase is separated by pipetting. The extraction is repeated three times. The extracts are combined, and evaporated under reduced pressure to dryness at a temperature below 60° C. The residue is dissolved in 2 ml. of methanol, and transferred to a small glass tube. This is repeated three times. The methanol extract is evaporated to dryness in the same way. The residue is dissolved in a small amount of methanol.

The methanol extract is placed on Toyo Roshi filter paper No. 51 (5 × 60 cm.), which has been pretreated with pyridine–acetic acid–water (1 : 10 : 89 v/v) just before use, at a distance of 8·5 cm. from the anode end. The paper is subjected to high-voltage paper electrophoresis for 2 hr., using *n*-hexane as refrigerating insulator. Operating voltage is 2,500–3,000 V., current 8–12 m.amp. Metadrenaline migrates about 40 cm. toward the cathode, and normetadrenaline about 42 cm., so that they are separated completely from other substances as well as from each other.

After the paper is dried at 60° C. for 20 min., diazotized *p*-nitroaniline is sprayed on both sides of the paper. Both metabolites react to give a violet colour. The paper is dried again, the bands of methoxycatecholamines are cut into pieces, and eluted with 4 ml. of alkaline methanol (methanol–2 per cent sodium carbonate, 2 : 1 v/v) for more than 1 hr. These eluates are assayed in a Beckman spectrophotometer model *DU* at the wave-length of 520 mμ. The uncoloured part of the paper is treated similarly and serves as a blank.

Extraction (using *n*-butanol, *iso*butanol *iso*amylalcohol were examined) of the urine was found inadequate, for inorganic salts were extracted together, which interfered seriously with further procedures. The metabolites were not extracted into ethyl ether or ethylene dichloride as efficiently as into ethyl acetate. Purification of *O*-methylated catecholamines with ion-exchange resin was also unsuccessful.

High-voltage paper electrophoresis was found most suitable for the separation of the amines in the extract. Paper chromatography using several solvent systems did not result in good separation of them, as compared with the electrophoretic method.

When the urine was not hydrolysed, the estimated values were much lower than those after hydrolysis. Hydrolysis at approximately *p*H 0 (checked by test paper) resulted in lower yields as compared with that at *p*H 1·0. In accordance with Goodall *et al.*[4], incubation of urine with bacterial β-glucuronidase gave rise to no increase in metadrenaline and normetadrenaline values.

The minimal quantity detectable by the method was 0·2–0·3 μgm. for both amines. It was found after repeated estimations that errors of about ± 7 per cent are inevitable in the determination. The overall recovery of the amines added to urine was 80–90 per cent.

Twenty-two urine specimens from normal subjects and various patients were assayed (Table 1). Normal human beings excrete 100–300 μgm. of metadrenaline and almost the same amount of normetadrenaline daily in the urine. Patients with essential hypertension or hyperthyroidism excrete approximately the same quantities of metabolites as normal subjects. Two patients with phæochromocytoma excreted abnormally large quantities of metadrenaline and normetadrenaline.

Our method is relatively simple, reproducible and sensitive enough to estimate such low concentrations of metadrenaline and normetadrenaline as are excreted in the urine of normal human beings.

We are indebted to Dr. Julius Axelrod for his gift of metadrenaline and normetadrenaline.

Effect of Pituitary Growth Hormone on Cholesterogenesis

It has been reported earlier that injections of anterior pituitary growth hormone into adult female rats cause a decrease in the rate of synthesis of fatty acid and an increase in the rate of cholesterogenesis in the liver[1]. Inverse relationships of this type have also been described as occurring in diabetic rats[2] and in normal rats injected with thyroxine[3]. These results were obtained using labelled acetate as substrate. The availability of labelled mevalonic acid now permits some dissection of the pathway involved.

The rats used were adult females injected with 1 mgm. pituitary growth hormone 6 hr. before killing. After killing, the livers were rapidly removed and slices prepared with the aid of a Stadie–Riggs[4] microtome. 400 mgm. of slices were suspended in 5 ml. Krebs–Ringer bicarbonate buffer containing either 0·6 μc. sodium acetate-1-^{14}C or *dl*-sodium mevalonate-2-^{14}C with no carrier added. The flasks were gassed with an oxygen/carbon dioxide mixture (95 : 5) and were incubated for 3 hr. After this period the slices were collected by centrifugation and then suspended and homogenized in 4 ml. of 5 per cent trichloracetic acid. The precipitate obtained from this was washed with 5 per cent trichloracetic acid and then water, the supernatant being discarded in each case. The precipitate was then extracted with alcohol/ether (3 : 1) and, finally, ether. The combined organic solvent layers were evaporated and the residue re-extracted with petroleum ether (40°–60°). After separation of the phospholipids as the magnesium complexes, the supernatant was saponified and the free cholesterol extracted and precipitated as the digitonide. Fatty acids were then separated after acidifying the supernatant fraction. Samples from each of the separated fractions were counted as infinitely thin layers in a 'Tracerlab' *SC*–16 windowless counter.

The results showing the incorporation of the two radioactive substrates into fatty acids, phospholipids and cholesterol are given in Table 1.

It will be seen that the incorporation of both mevalonate and acetate carbon into phospholipids is reduced in animals treated with growth hormone although, as might be expected, the reduction is much greater in the case of acetate. The incorporation of acetate-carbon into the fatty acid fraction (derived mainly from glyceride and cholesterol esters with some free fatty acid) is also much reduced in the rats treated with growth hormone and to about the same degree as the reduction found in the fatty acids of the phospholipid fraction. However, the incorporation of carbons from mevalonic acid into the ester fatty acids appears to be slightly accelerated in the animals treated with hormone. This somewhat surprising result may mean that the fatty acids formed from mevalonate carbons differ from those derived from acetate.

Finally, it can be seen that while the incorporation of acetate carbon into cholesterol is speeded up by a factor of 4–6 times in rats treated with growth hormone, the rate of incorporation of mevalonate remains unchanged. Thus, the stimulating effect of the hormone on the rate of synthesis of cholesterol

Table 1. Effect of Pituitary Growth Hormone on the Incorporation of Mevalonate-2-^{14}C and Acetate-1-^{14}C into Cholesterol, Phospholipids and Fatty Acids of Liver Slices

appears to be located in that part of the pathway between acetyl coenzyme A and mevalonic acid. The earlier part of this pathway, leading to the formation of β-hydroxy-β-methyl-glutaryl co-enzyme A, is common to both cholesterol synthesis and acetoacetate formation. Since it has previously been shown that in rats treated 6 hr. previously with growth hormone the rate of hepatic acetoacetate output is much reduced[5], it would appear that the increased rate of formation of cholesterol is due to a diversion of the β-hydroxy-β-methyl-glutaryl co-enzyme A from acetoacetate formation, and an increased rate of its reduction to mevalonic acid by its reductase. The hormone appears to have no effect on the subsequent condensation of the mevalonate molecules to cholesterol. This finding is in keeping with the conclusion of Bucher, Overath and Lynen[6], who have suggested that the decreased rate of formation of cholesterol in starving animals is due to a reduction in the activity of the β-hydroxy-β-methyl-glutaryl co-enzyme A reductase.

Blockage of Transformation of Tryptophan to Nicotinic Acid by Experimental Hepatitis in Mice

THE existence of biochemical lesions in the complicated path from amino-acid to vitamin in man, and in experimental animals suffering from various diseases, has been identified by a number of authors analysing urinary metabolites of tryptophan by means of paper and column chromatography[1-6]. These analyses have shown an accumulation in the urine of metabolites proximal to the lesion.

In the present work we have studied the chromatographic picture of urinary metabolites of the tryptophan–nicotinic acid cycle both in normal mice and in mice with experimental hepatitis induced by mouse hepatitis virus strain 3 (*MHV*-3) at different stages of multiplication, in an attempt to identify the level of a possible biochemical lesion. Since the spontaneous elimination of urinary metabolites of tryptophan is small, we have preferred to follow them after a dose of L-tryptophan.

Mice of Swiss stock, weighing about 15 gm. and fed on Voght and Moller's diet were used. The programme of one of our experiments was as follows: 100 mice were divided into 5 (*A*, *B*, *C*, *D*, *E*) groups of twenty animals. Ten mgm. of L-tryptophan were injected subcutaneously into each animal in order to maintain the normal excretory pattern. After five days, mice from groups *A*, *B*, *C* and *D* were inoculated by the intraperitoneal route with 100 LD_{50} virus *MHV*-3.

To study the excretory pattern of metabolites of the biological degradation of tryptophan in different phases of the multiplication of the virus, a second dose of tryptophan was given to groups *A*, *B*, *C* and *D* at 12, 24, 48 and 72 hr. respectively. The mice in group *E*, not inoculated with the virus, were also given a second dose of tryptophan simultaneously with group *A*.

In the 24 hr. following the injection of tryptophan, the urine from each group of mice was collected in opaque glass vessels containing 2 ml. of 50 per cent glacial acetic acid (1: 1), and was diluted with water to a volume of 5 ml. The urine was then centrifuged. Dalgliesh's[7] method of chromatographic analysis for urinary metabolites in the tryptophan–nicotinic acid cycle was used, but omitting the absorption on carbon and the subsequent treatment with phenol.

The analysis of the urine of the control mice (*E*) injected with L-tryptophan showed the appearance of conjugates of the kynurenines (R_F 0·1–0·15) of kynurenic and xanthurenic acids, of acetylkynurenine and sometimes of free anthranilic acid.

In contrast, the urine of the mice inoculated with the virus showed the presence of all these metabolites (except anthranilic acid) in greater and more constant quantities, and in addition, the presence of kynurenine and of 3-hydroxykynurenine in notable quantities. The chromatographic picture also showed the progressive growth of the metabolic lesion paralleling the aggravation of the viral hepatic lesion.

Other metabolites, such as 3-hydroxyanthranilic acid, have never been observed on normal mice or in mice inoculated with the virus.

From the results obtained, we conclude that in mice with experimental hepatitis caused by the *MHV*-3 virus a biochemical lesion occurs at the level of enzymic transformation of 3-hydroxykynurenine to 3-hydroxyanthranilic acid.

Sucrases in *Phaseolus vulgaris*

DURING work on the oligosaccharides of *Phaseolus vulgaris*, L. (namely, verbascose, stachyose, raffinose and sucrose[1-3]—the raffinose family of oligosaccharides[1]), an examination was made of the enzymes catalysing the hydrolysis of these saccharides. α-Galactosidase and sucrase activities were found in the ungerminated and germinated seeds.

The α-galactosidase activity proved to be typical of that described by Courtois *et al.*[4-7] in extracts of coffee and haricot beans and by Pridham[8] in extracts of *Vicia faba*, since it removed galactose from verbascose, stachyose and raffinose *in vitro* to give sucrose. From the higher homologues, verbascose and stachyose, the galactose was removed stepwise (cf. Courtois *et al.*[4]), producing stachyose and raffinose respectively as intermediates. The α-galactosidase activity was found in extracts of both the embryos and cotyledons in the ungerminated and germinated seeds.

On the other hand, two types of sucrase activity were found. These differed in both properties and occurrence; one activity appeared to resemble the invertases previously demonstrated in extracts of other seeds[9–11] and in extracts of yeast[12], while the other activity ('alkaline sucrase') differed from these invertases in optimal *p*H of action and its apparent specificity.

The enzyme extracts were prepared by homogenizing fresh plant material with water or 0·01 *M* phosphate buffer, *p*H 7·2–7·5 (1/3–1/2 vol. for embryos and 3 vol. for cotyledons), centrifuging at 34,000*g* for 30 min. at 0° C. and dialysing the supernatant solution against 0·01 *M* phosphate buffer, *p*H 7·0. Usually for qualitative work an equal volume of enzyme extract was added to a volume of buffer 0·2 *M* containing 0·2 *M* substrate to give the required *p*H after mixing. The enzyme action was followed by conventional chromatographic techniques which would detect 1–2 per cent hydrolysis[13] of the substrates. For quantitative work the reducing sugars produced were estimated by the Nelson–Somogyi method[14] after removal of the protein from the extracts by precipitation with zinc sulphate–barium hydroxide[15].

The 'alkaline sucrase' activity could be found in extracts prepared from embryos and cotyledons of ungerminated and germinated seeds but could best be prepared from embryos of steeped seeds. On 0·1 *M* buffered sucrose solutions at 25° C., the activity was found to have a narrow optimal *p*H range with a maximum at *p*H 7·8. The activity was not lost on dialysis and phosphate ions were not necessary for its action since it functioned equally well on sucrose in borate buffer (0·1 *M*); however, it was inhibited by *tris*(hydroxymethyl)aminomethane (*tris*)-hydrochloric acid and *tris*-maleate buffers. An extract of 'alkaline sucrase' prepared as described from steeped embryos had an initial rate of inversion of sucrose of 3×10^{-4} moles per hr. on 0·1 *M* sucrose, *p*H 7·8 at 25° C., which fell off to a low rate after 24 hr. of reaction and 40–50 per cent inversion of the sucrose. The extract showed no action towards stachyose, raffinose, 1-kestose, and, moreover, showed no transferase activity[13] during its action on strong (20 per cent) sucrose solutions. A small amount of hydrolysis observed in the experiments with stachyose and raffinose was shown to be due to the action of the α-galactosidase. This produced some sucrose which was then hydrolysed by the 'alkaline sucrase'. No manninotriose or melibiose were found in these experiments. These oligosaccharides would be found if invertase were present (as in the experiments with germinated embryos). The extract had some action on maltose at *p*H 7·8 but had no action on melezitose. The rate of hydrolysis of the maltose was 0·41 the rate of hydrolysis of sucrose by this extract under similar conditions. However, after purification by an ammonium sulphate fractionation, the rate of maltose hydrolysis was 0·2 of the rate of hydrolysis of sucrose. This separation indicated that two different enzymes were present, namely, sucrase and maltase, since if only one enzyme were involved the ratio of rates of hydrolysis on the two substrates would remain the same after purification.

On the other hand, the sucrase similar to other invertases could only be found in extracts prepared from germinated embryos (cf. Pridham[8]). This activity had a broader optimal *p*H range with a maximum at *p*H 4·9–5·0. An extract, prepared as described from germinated embryos, had an initial rate of inversion of sucrose approximately the same as that of the 'alkaline sucrase' extract prepared from steeped embryos. However, the rate of action was linear with time up to 90 per cent inversion of 0·1 *M* sucrose and the sucrose was completely inverted after 12–14 hr. The extract hydrolysed stachyose and raffinose, producing manninotriose and fructose, and melibiose and fructose respectively; however, the α-galactosidase activity which was also present in the extract hydrolysed the oligosaccharides further to give galactose, glucose and fructose as the final hydrolysis products. The extract also hydrolysed 1-kestose, maltose and melezitose and showed characteristic transferase action on strong (20 per cent) sucrose solutions. The hydrolysis of raffinose and melezitose would indicate that both β-fructosido—and α-glucosido—invertases were present in the extract.

From these facts it seems, therefore, that the new enzyme 'alkaline sucrase' is not: (*a*) an α-glucosido- or a β-fructosido-invertase since it does not attack melezitose and raffinose, which are respective substrates for these enzymes; (*b*) an α-glucosidase proper since the enzyme does not attack melezitose and maltose; or (*c*) sucrose phosphorylase because the enzyme hydrolysed sucrose in the absence of phosphate ions. It is concluded that the observed activity must result from the presence of a new type of sucrase, apparently highly specific for sucrose. The metabolic significance of this enzyme is not yet known.

A sucrose-specific enzyme has been found in a haploid hybrid *Saccharomyces* strain by Hestrin and Lindegren[16], and it is also interesting to note that two phytases having different *p*H optima and two lipases having different *p*H optima have been reported to occur in germinating lettuce seeds[17].

We wish to express our thanks to Dr. J. B. Pridham for a sample of verbascose and to Dr. J. Edelman for a sample of 1-kestose.

PHYSIOLOGY

Active Cation Transport as a Pace-maker of Respiration

INHIBITION of metabolism leads to a gain of sodium and a loss of potassium by cells, and it is widely realized that the maintenance of concentration gradients of these ions between cells and plasma depends on a supply of energy from metabolism. This holds true for red cells that derive energy from glycolysis, for the majority of tissues that depend on respiration and for the few cells and tissues that actively transport cations with energy derived from either metabolic pathway. Cells appear to transport cations actively only when adenosine triphosphate (ATP) is being produced *in situ* or is supplied from an exogenous source, such as by injection into poisoned squid giant axons[1] or by introduction into red cells ghosts by the technique of 'reversible hæmolysis'[2]. ATP is necessary, therefore, and its rate of production either by substrate or oxidative phosphorylation is one of the factors that determines the rate at which active transport occurs.

The converse situation is that the rate of metabolism might be regulated by the rate of active transport. This is feasible in respiring cells because respiration is governed by the concentration of adenosine diphosphate (ADP) which is determined in turn by the activity of the various mechanisms causing the hydrolysis of ATP. Since one of these is the fission of ATP due to active transport, it is of interest to test experimentally if the cessation of active transport by specific inhibitors which do not directly inhibit respiration causes a fall in the rate of respiration.

Slices of brain and kidney cortex from rabbits are suitable experimental tissues, because they have a high consumption of oxygen, on which active cation transport depends[3], and also the rates of exchange of their sodium and potassium are high. The maintenance of the intra-cellular potassium concentrations has therefore been compared with the Qo_2 (µl./mgm. dry wt./hr.) after incubations of 1 hr. in a saline medium containing glucose (150 m*M* sodium chloride, 5 m*M* potassium chloride, 2 m*M* magnesium chloride, 10 m*M* sodium phosphate *p*H 7·4, 10 m*M* glucose). Two ways of abolishing active transport were tested at 37° C.: (1) exposure of the slices to the cardiac glycoside, ouabain; (2) replacement of sodium of the medium with choline. With brain slices, 5 µ*M* ouabain caused falls of 70 per cent in the potassium concentration (from 360 to 100 m. equiv./kgm. dry wt.) and of 50 per cent in the Qo_2 (from 16·7 to 8·0). Replacement of sodium of the medium with choline caused a fall in Qo_2 to 8·8 and a fall in potassium concentration to 110 m.equiv./kgm. dry wt.; no further fall occurred with 5 µ*M* ouabain. Similar results were obtained with kidney slices, in which 25 µ*M* ouabain caused a fall of 64 per cent in the potassium concentration (from 420 to 150 m.equiv./kgm. dry wt.) and of 45 per cent in the Qo_2 (from 13·2 to 7·2). In a choline (sodium-free) medium, the Qo_2 of 8·4 and the potassium concentration of 120 m.equiv./kgm. dry wt. were unchanged by ouabain. The fall in Qo_2 caused by ouabain thus occurred only in the presence of sodium in the medium and is of the same magnitude as the reduction caused by the removal of sodium.

To see if the component of the tissue which is sensitive to ouabain and sodium still controlled respiration after breaking up the cells, homogenates of brain cortex were made in four solutions so as to introduce (0·15 *M* sodium chloride) or to exclude (0·15 *M* potassium chloride, 0·15 *M* choline chloride and 0·25 *M* sucrose) sodium. Each solution also contained 2 m*M* magnesium chloride, 10 m*M* glucose and 2·5 m*M* dipotassium hydrogen phosphate. Incubations were then made with and without ouabain (5 µ*M*) both in the absence of sodium and after the addition of sodium to part of the sodium-free homogenates. Table 1 shows that, irrespective of the method of preparation, homogenates in a high-sodium medium were sensitive to ouabain, the Qo_2 being reduced by 32–48 per cent (line *c*). Omission of sodium from the medium caused falls in Qo_2 of 33–42 per cent (line *g*) and, in the absence of sodium, no further fall in Qo_2 was caused by ouabain (line *f*). The respiration of homogenates was thus equally reduced by ouabain and the deprivation of sodium in a way comparable to that of slices.

Since systems utilizing ATP are some of the most important regulators of cell respiration[4], it seems likely that the reduction in Qo_2 is due to the sensitivity to ouabain and sodium of one or more of the reactions leading to the formation of ADP from ATP. Recent work on adenosine triphosphatases in red cells[5], kidney[6], brain[7] and crab nerve[8] has indeed shown the existence of ATP-hydrolysing systems which require sodium for activation and which are inhibited by ouabain, and it has been suggested that they are intimately associated with active transport. The quantitative relation between the amount of ATP split and the amount of material actively transported is difficult to assess because of insufficient information of the intracellular concentrations of ATP, ADP and orthophosphate, and estimates based on the standard free energy of hydrolysis of ATP are dubious[9]. Nevertheless, the results with slices show that the maintenance of a high tissue-potassium concentration and the Qo_2 are reduced in a parallel manner by ouabain and the deprivation of sodium, suggesting a partial control of respiration by the transport mechanism. The stoppage of active transport reduces the demand for ATP and therefore explains the concomitant fall in Qo_2 of 40–50 per cent. Similar results with homogenates suggest the possibility either that other ATP-hydrolysing reactions are also sensitive to ouabain and sodium or that the transport mechanism continues to hydrolyse ATP in broken cells. The latter possibility would seem more likely in view of the correlation of the properties

Table 1. DECREASE IN Qo_2 OF BRAIN HOMOGENATE IN THE PRESENCE OF OUABAIN AND ON THE OMISSION OF SODIUM FROM THE MEDIUM. (*S.E.* of the means are given)

			Qo_2			
Main solute in the solution in which homogenate made			Sodium chloride	Potassium chloride	Choline chloride	Sucrose
No. of experiments			3	5	4	4
High sodium medium (112–150 m*M* sodium)	no ouabain	(*a*)	2·70	2·62 ± 0·23	2·33 ± 0·19	1·65 ± 0·11
	with ouabain	(*b*)	1·40	1·69 ± 0·07	1·59 ± 0·14	1·09 ± 0·06
	fall due to ouabain	(*c*) = (*a* − *b*)	1·30	0·93 ± 0·23	0·74 ± 0·18	0·56 ± 0·08
Sodium-free medium	no ouabain	(*d*)	—	1·57 ± 0·14	1·49 ± 0·10	1·11 ± 0·10
	with ouabain	(*e*)	—	1·51 ± 0·11	1·43 ± 0·07	1·00 ± 0·06
	fall due to ouabain	(*f*) = (*d* − *e*)	—	0·06 ± 0·10	0·06 ± 0·09	0·11 ± 0·05
Fall due to omission of sodium from medium	no ouabain	(*g*) = (*a* − *d*)	—	1·05 ± 0·32	0·84 ± 0·20	0·54 ± 0·08

of the active cation transport system in intact red cells with those of the ATP-hydrolysing system in fragment red-cell membranes[5].

The parallelism of the effects of ouabain and sodium on the maintenance of the tissue-potassium concentration and on the Q_{O_2} therefore suggests the tentative conclusion that an ATP-hydrolysing system associated with the active transport of cations may act as a pace-maker for about half the respiration of brain and kidney cortex.

Effect of Thyroxine and 2,4-Dinitrophenol on the Rate of Utilization of Glucose

IT has long been recognized that 2,4-dinitrophenol increases oxidative metabolism. The increase of oxygen consumption after the addition of 2,4-dinitrophenol (DNP) is explained as being a result of dissociation between oxidative and phosphorylative processes. Similarly, thyroxine accelerates oxidation by uncoupling an oxidative phosphorylation. But DNP does not prevent the phenomena of hypothyroidism other than basal metabolism[1], and fails to change lipid metabolism[1,2] and nitrogen excretion, the effects of which are known to follow thyroxine administration[1]. Therefore, it was interesting to compare the effects of these agents on carbohydrate metabolism.

In the present experiments I studied the influences of DNP and thyroxine on the rate of utilization of glucose in normal and thyroidectomized rabbits (120 days after operation). The utilization of glucose was determined from the rapid intravenous glucose tolerance test (GTT) which was performed 4 hr. following the subcutaneous administration of DNP (7·5 mgm. rabbit) or thyroxine (0·25 mgm./kgm. body-weight). Immediately after a fasting blood sample of venous blood had been obtained from the vein of the ear, 0·5 gm./kgm. body-weight of glucose was injected intravenously during 10 ± 5 sec. The blood samples for estimation of blood glucose were drawn from the vein of the other ear at intervals of 10, 20, 30, 45, 60, 75, 90 min. after the end of the injection of sugar. From this intravenous GTT the rate of utilization of glucose may be expressed by determining the assimilation coefficient of glucose (K) as was described in previous papers[3,4].

The results of my experiments are summarized in Table 1. 4 hr. after the administration of thyroxine and DNP the fasting blood-sugar levels were slightly increased both in normal and thyroidectomized rabbits. In intravenous GTT it was observed that thyroxine accelerated the utilization of glucose in both groups of experimental animals as early as 4 hr. after administration. Similarly, DNP increases the rate of utilization of glucose in normal and thyroidectomized rabbits. The results of these observations suggest that the influence of thyroxine and DNP on carbohydrate metabolism is similar, in contrast to their effects on lipid or protein metabolism. Both agents accelerate the rate of utilization of glucose, but the precise mechanism of this action is not clear. The increase in the assimilation coefficient of glucose after the addition of DNP may be explained by insulin mobilization (probably due to its hyperglycæmic effect), as suggested by Hetényi *et al.*[5], or by the acceleration of the transfer of sugar across the muscle cell-membrane as observed by Randle *et al.*[6,7]. Further, it is interesting to note that thyroxine accelerates the utilization of glucose as early as 4 hr. following its injection, without any protracted latent period, which is in agreement with the experiments of Christophe and Mayer performed on rats[8].

Determination of Spontaneous Plasma Fibrinolysis by a Practical Procedure

IN a recent review I analysed present aspects and principles of the various methods that are generally used for assessing the phenomenon of proteolysis in the blood. The extensive significance of *in vitro* determination of whole plasma spontaneous fibrinolysis, which expresses a more faithful and exact picture of the evolution of the fibrinolytic mechanism in the circulating blood, was emphasized[1].

As is known, the determination of the spontaneous fibrinolysis of the whole blood or of plasma in physiological conditions takes a long time[2,3]. Repeated attempts to shorten the time of lysis by a strong dilution of plasma[4] or the carrying out of the low-temperature technique[5] did not solve the problem sufficiently in so far as to establish an accepted practical method for the assessment and computation of the phenomenon of fibrinolysis. The only useful determination is obtained with the euglobulin method in the plasma, which according to different techniques that are described, offers an estimate of the phenomenon within 3–24 hr.[6-9]. This method is characterized by an expression for the spontaneous fibrinolysis of the plasma, but there are theoretical and practical considerations on the basis of which it becomes questionable if, and to what extent, the method is representative.

In this communication a practical procedure is described for the determination of spontaneous fibrinolysis in the whole plasma, based on the observation that the time of lysis of plasma under similar conditions of dilution, *p*H, recalcification and temperature is markedly shortened, if at first the received whole blood is diluted immediately in an appropriate buffer solution and, thereafter, the fibrin-clot is formed by recalcification of the supernatant fluid phase. Under these conditions the retraction of the clot is insignificant and thus the end-point of lysis can be observed.

Reagents :

(1) Buffer diethylbarbiturate (*p*H 7·40) :	
Sodium diethylbarbiturate	4·12 gm.
M/10 hydrochloric acid	144·00 ml.
Potassium oxalate	0·50 gm.
Sodium chloride	5·50 gm.
Water distilled at	1000·00 ml.
(2) *M*/600 calcium chloride	

With a 1·0 ml. calibrated precision-syringe, 0·5 ml. of venous blood is withdrawn and transferred immediately into a small tube containing 2 ml. of the buffer, which previously has been placed in a container of melting ice. The transfer is performed gently, while the mixing takes place automatically. The tube is centrifuged for 1 min. at 3,500 r.p.m. From the supercooled layer 1·0 ml. is taken at once and placed in a tube which is immersed in a 37° C. water-bath containing 1·0 ml. from the solution of *M*/600 calcium chloride. Clotting takes place in a few minutes. Time of lysis is determined by frequent checking.

The time of clot lysis varied between 6 and 18 hr. for almost the total series of cases, as this is calculated from the samples that were taken at the ninth hour, from 50 normal subjects of both sexes, 20–45 years of age (Fig. 1). In two cases a time less than 6 hr. (3 and 5 hr. respectively) was observed while for only 4 other cases the time of lysis was more than 18 hr. (21, 26, 27 and 32 hr.). The repeated trial of the method is satisfactory, because the different time of clot-lysis obtained in repeated determinations of the same plasma did not exceed 10 per cent.

The time-values obtained are much lower than with any hitherto known method of determination in whole plasma and comparable to the euglobulin method. The euglobulin method is used by many research workers as a method for the determination of the spontaneous fibrinolytic activity of the plasma, and this cannot be ascertained by virtue of the nature of the method, because lysis is only countable in the euglobulin fraction. These observations are of special import, particularly after recent work[6] showing that findings on the same samples of blood that are registered in the whole plasma and in the euglobulins fraction are not always in an analogous ratio. For example, examination of a hepatic patient, though it disclosed an increased fibrinolytic action in the whole plasma, did not record deviations worthwhile from the physiological point of view, by the method of the euglobulins.

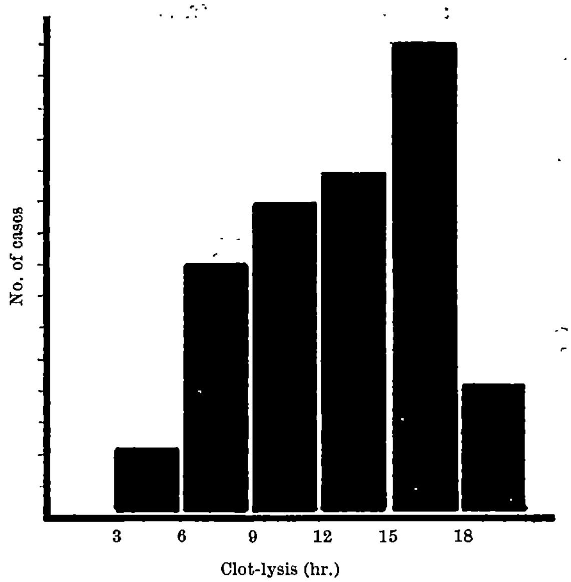

Fig. 1

The suggested procedure for measuring fibrinolytic activity of whole plasma represents a rapid technique and its simplicity is advantageous. This method requires 0·5 ml. of blood, the lysis of the fibrin clot is estimated accurately in a physiological *p*H and reproducibility is satisfactory.

Effect of Bee Venom on Concentration of Blood Glucose and Liver Glycogen in Rabbits

COBRA venom and scorpion toxin are known to cause hyperglycæmia[1] whereas the *Walterinnesia* venum produces hypoglycæmia.

In the present experiments it was shown that bee venom, the effects of which resemble in many ways those of cobra venom, also causes hyperglycæmia and loss of liver glycogen. The blood glucose was determined by the Hagedorn and Jensen method[2] ; the liver glycogen after hydrolysis of the removed livers by the method of Good, Kramer and Somogyi[3].

Fig. 1 illustrates the hyperglycæmia produced by a sub-lethal dose of 5 mgm. bee venom injected subcutaneously into a 2-kgm. fasting rabbit. The effect did not occur when the injections were made into immunized rabbits.

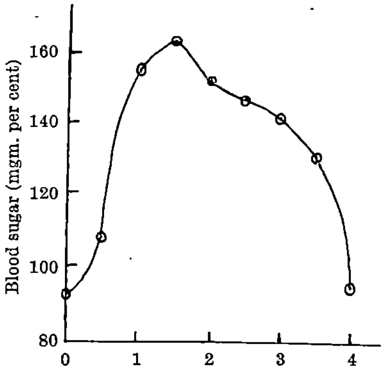

Fig. 1. Changes in blood-sugar level caused by injection of sublethal dose of bee venom

The fall in liver glycogen produced by 5 mgm. bee venom is illustrated for two groups of experiments. For each group five rabbits were used, one as a control, and the other four were killed 1, 2, 3 and 4 hr. after the injection and the liver removed.

Table 1. EFFECT OF SUBLETHAL DOSE

Time after injection (hr.)	Control	Liver glycogen (mgm./100 gm.) (mean value)	
		Experiment 1	Experiment 2
0	164·66	166·33	159·66
1	164	153·66	143·33
2	162	131	121·33
3	164	129·66	119
4	159	119·66	118

Since the maximal fall in liver glycogen occurred during the second hour, mobilization of liver glycogen may fully account for the hyperglycæmia, which was maximal 1½ hr. after the injection. The effect may be a direct action of bee venom on the liver, or brought about indirectly by the release of adrenaline from the suprarenals, since Feldberg[4] has shown that bee venom as well as cobra venom injected into the cœliac artery of the cat produced a sustained release of adrenaline from the suprarenals.

Action of the Hypothalamus

EXPERIMENTS with an analogue model of the heart, demonstrated by me[1], show that a pulse may arise, in a fluid-filled elastic system, in either of two ways: in the first, energy is cycled into the system from a mechanical source, corresponding to the physicochemical contraction of the ventricles ; in the second, pulsation can be derived from the static head of pressure with the aid of a length of elastic tubing arranged as a wave guide. The latter device, termed an 'oscillator', may be employed to time delivery of energy from the external source, in such a manner that the system is self-oscillating and that the two pulses, of differing origin, are synchronous.

In lesions of the conducting system of the heart, the coronary arterial system behaves, apparently, as an oscillator that utilizes the static head of pressure of the blood to develop a pulse. The same phenomenon is likely to occur at the circulus arteriosus, under normal conditions, however, due to the negative pressure in the internal jugular vein.

Examination of this possibility has led to the following explanation of the action of the hypothalamus :

Independently of the pulse from the heart, a vascular pulse originates in the perforating branches of the circulus arteriosus and is conveyed to the nerve cells in the nuclei of the hypothalamus. Provided the leading edge of the wave is sufficiently steep, the cells are excited to generate electrical impulses, which are utilized by the brain as timing signals.

There are at least two types of excitation. One, in the anterior hypothalamus, is associated with a positive temperature coefficient of frequency: a second, in the posterior hypothalamus, with a negative temperature coefficient of frequency. A third type of excitation probably occurs in the intermediate group of nuclei, with frequency unrelated to temperature. Similar physical relationships are found in connexion with the vibration of piezo-electric crystals, where the direction of the slice, with relation to the axes of the crystal, determines the sign of the temperature coefficient of frequency.

The importance of the structures around the circulus arteriosus suggests that the latter is the most important site in the body at which self-oscillation occurs. The major function of the sinus caroticus is, presumably, that of monitoring the diastolic blood pressure, to ensure stable operating conditions for the circulus arteriosus. Slight variations of frequency will result from changes of venous pressure in the thorax, due to respiration. This effect can be displayed on the model.

To prevent interference between the waves produced by the heart and those generated at the circulus arteriosus, it is essential that there be a co-ordinating mechanism. On one hand it is well known that signals—or nerve impulses—travel from the hypothalamus to the heart by way of the autonomic nervous system. On the other, it would appear that the signals from the heart to the hypothalamus are actually the heart sounds, conducted by the bones of the thorax and vertebral column to the region of the hypophyseal fossa, where they exert a 'pulsactor effect', of which the significance is explained elsewhere[2], on the surrounding vascular structures.

Examples of systems in which two synchronizing signals require co-ordination are to be found in radar. In one example, the transmitter takes signals from the master timing signal generator and, in addition, synchronizing signals from the indicator of the receiver : the more stable system determines the frequency. Applying the analogy to the human body, the hypothalamus is identified as the master timing signal generator.

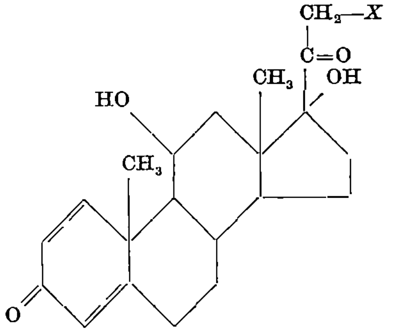
PHARMACOLOGY

Amino-derivatives of 11β,17α,21-Trihydroxy-3,20-Dioxo-1,4-Pregnadiene

The skeleton of corticosteroids was systematically modified, mainly in order to study the changes in the pharmacological effect of the compounds.

One of the objects of our experiments was the exchange of the C_{21} hydroxyl group of corticosteroids by amino- and substituted amino-groups, respectively.



(*a*) $X = -O-SO_2-C_6H_4-CH_3$; (*b*) $X = -I$; (*c*) $X = -1$ piperidyl; (*d*) X = 4-morpholyl; (*e*) $X = N(C_2H_5)_2$.

The 21-tosylate (*a*) of 11β,17α,21-trihydroxy-3,20-dioxo-1,4-pregnadiene and the -21-iodine compound (*b*)[1] derived from it served as initial substances in preparing the compounds mentioned.

One mole of the -21-tosylate of 11β,17α,21-trihydroxy-3,20-dioxo-1,4-pregnadiene (*a*) was treated in a tetrahydrofuran solution, in a nitrogen current, with two moles of piperidine at 55° C. for 5 hr. On dropping the reaction mixture into water, 11β,17α,dihydroxy-3-20-dioxo-21(1-piperidyl)-1,4-pregnadiene (*c*) was obtained in 93 per cent yield, in crystalline form; on recrystallizing from a mixture of tetrahydrofuran and petroleum ether, melting point 181° C. (decomposition) was found. Analysis: calculated, C 73·06; H 8·6 per cent; found, C 73·00; H 8·9 per cent.

Compound (*c*) has also been prepared by reacting one mole of the corresponding iodine compound (*b*) with two moles of piperidine under conditions similar to those mentioned. Melting point of product: 181° C. (decomposition). Melting point of the hydrochloride: 236–238° C. (decomposition). Analysis: calculated, C 67·31; H 8·1; Cl 7·6 per cent; found, C 67·07; H 8·1; Cl 7·8 per cent.

In a similar way, 11β,17α,-dihydroxy-3,20-dioxo-21-(4-morpholyl)-1,4-pregnadiene (*d*) was obtained from the tosylate (*a*) and iodine compound (*b*). Melting point 191–193° C. Analysis: calculated, C 69·91; H 8·1 per cent; found, C 69·62; H 8·2 per cent. Melting point of hydrochloride: 235–237° C. (decomposition). Analysis: calculated, C 64·65; H 7·7 per cent; found, C 64·38; H 7·6 per cent.

Similarly to the above-mentioned compounds, 11β,17α,-dihydroxy-3,20-dioxo-21-diethylamino-1,4-pregnadiene (*e*) has been prepared. Melting point of hydrochloride: 227° C. (decomposition). Analysis: calculated, C 66·44; H 8·41; Cl 7·86 per cent; found, C 66·20; H 8·28; Cl 7·61 per cent.

C_{21}-amino -derivatives similar to the corticosteroid derivatives mentioned have also been prepared in an essentially similar way by E. J. Agnello and G. D. Laubach[2].

The compounds prepared by the foregoing technique were subjected to pharmacological tests in the form of bases insoluble in water and of water-soluble hydrochlorides, respectively. Compounds of gluco-corticoid activity are known to possess the general feature of containing oxo-groups on their C_3 and C_{20} atoms, a hydroxyl or oxo-group on their C_{11} atom and a double bond between C_4 and C_5. Also, a common property of these compounds is the hydroxyl function on C_{21}. The α-positioned hydroxyl on C_{17} is absent in the case of corticosterone of similarly gluco-corticoid effect, although only moderately active. Thus, all known efficient substances actually bear an oxygen atom on C_{21}.

The compounds mentioned previously were examined by comparison with the effect of prednisolone. These investigations were carried out by two methods. The accumulation of liver glycogen was investigated on suprarenal gland ectomized rats, extracting the deposited glycogen with trichloracetic acid and determining glycogen by turbidimetry. The antiphlogistic action of the compounds was examined by the method of rat foot œdema determination evolved by us[3]. Male rats were used in these tests.

The experimental results obtained by both methods disclosed activities of about 80 per cent in respect to prednisolone in the case of the C_{21} piperidine derivative (*c*), of the C_{21} morpholyl derivative (*d*) and of the hydrochlorides of these compounds. Further, it was found that, while on treating rats *per os* with prednisolone the activity of this substance was about 50 per cent of that observed in the case of subcutaneous injections, the water-soluble derivatives were resorbed in 90 per cent.

On the basis of our experiments we can thus state that the C_{21} amino-derivatives of prednisolone possess a gluco-corticoid activity corresponding to that of prednisolone itself. Accordingly, the function of C_{21} does not seem to be an indispensable pre-requisite of gluco-corticoid activity. It appears that its function can be replaced by an amino-group. The water-soluble salts of the compounds prepared in this way are similarly efficient. From the gastro-intestinal tract these latter compounds are more readily resorbed than prednisolone—a substance insoluble in water.

Our experimental results will shortly be published in detail.

Effects of Morphine-like Drugs in Chicks

Several workers[1–4] have used conscious chicks to study the actions of drugs. Chicks are particularly useful for drugs acting on the central nervous system, as their blood-brain barrier does not form until they are about 3 months old[5,6]. The effects of analgesic drugs on chicks were demonstrated at a meeting of the British Pharmacological Society[7] and are described here. Analgesic action was measured by the multiple toe-pinch method[8], which has been applied successfully to guinea pigs and rats. An untreated chick squeaks and shakes its foot when an artery clip is applied to one of its toes and these responses were used to test whether nociception was suppressed by drugs.

Morphine showed very low potency in suppressing these responses in chicks, in contrast with its potency in other species. While morphine (5–20 mgm./kgm.), subcutaneously or intraperitoneally, suppresses comparable responses in mice, rats and guinea pigs, 200 mgm./kgm. intravenously was required to produce similar analgesic action in chicks. This dose was very close to the *LD*50 and the therapeutic index was remarkably low. Table 1 shows the relatively low therapeutic indices (*LD*50/*ED*50) of the analgesic drugs tested and shows that morphine, methadone and 1-(β-diethylaminoethyl)-2-(*p*-ethoxybenzyl)-5-nitrobenzimidazole (20684) have a far lower potency in chicks than in guinea pigs. Codeine, however, is about equipotent in the two species.

Table 1. The Analgesic Actions and Toxicities of Morphine-like Drugs in Chicks and a Comparison with their Analgesic Potencies in Guinea Pigs (ref. 8)

Compound	Chicks			Guinea pigs
	Analgesic *ED*50 (mgm./kgm.) intravenous	*LD*50 (mgm./kgm.) intravenous	$\frac{LD50}{FD50}$	Analgesic *ED*50 (mgm./kgm.) subcutaneous
Morphine	230	305	1·33	6·3
Methadone	>18	24	<1·33	3·0
Pethidine	>40	42	<1·07	20·4
Codeine	26	45	1·73	25·0
20684	3·2	>20	>6·25	0·0032

During this work, it was observed that the intravenous administration of morphine-like drugs quickly produced characteristic postural and behavioural effects in the chicks. These effects occurred at doses lower than those required to suppress responses to noxious stimuli. The chick exhibited marked ptosis, became restless and stiff-legged. Then it sat down with its feet spread apart and its back at 30–50° to the horizontal (Fig. 1). Some chicks whined occasionally and the intensity of their cries became stronger on provocation. These effects sometimes persisted for several hours but could be antagonized within a few minutes by nalorphine (50–100 mgm./kgm.), given subcutaneously or intravenously. Table 2 shows the approximate doses of analgesic drugs producing these characteristic and postural effects. Among many drugs of other types investigated, only atropine produced comparable postural effects.

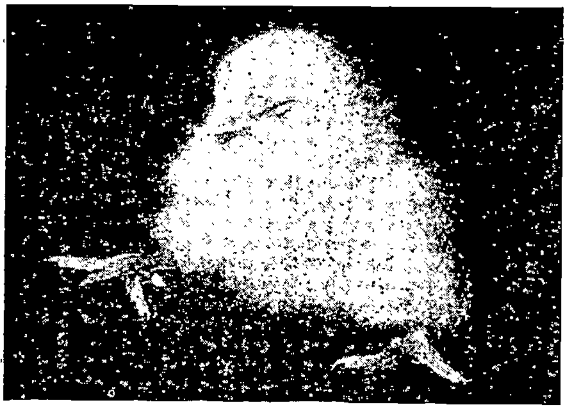

Fig. 1

Table 2. Approximate Minimal Doses of Analgesic Drugs producing Characteristic Postural Effects in Chicks

Compound	Dose (mgm./kgm.) intravenous
Morphine	20·0
Methadone	5·0–10·0
Pethidine	10·0
Codeine	15·0–20·0
20684	0·05

In conclusion, morphine and related drugs show only slight anti-nociceptive properties against acute mechanical stimuli in chicks, but cause postural and behavioural effects at low doses. Thus, in this species the side-effects of these drugs are more apparent than their anti-nociceptive action. The postural and other effects described appear to be characteristic of morphine and related drugs.

HÆMATOLOGY

Hæmoglobin *F* and the Genetic Control of Protein Structure

The publication of a hypothesis concerning hæmoglobin synthesis presented recently in *Nature* by Drs. Zuelzer and Robinson[1] prompts me to comment briefly. Their article concerns the genetic control of the synthesis of the peptide chains of the human hæmoglobins : A (adult) = $\alpha_2\beta_2$, F (fœtal) = $\alpha_2\gamma_2$, and A_2 (the minor adult hæmoglobin) = $\alpha_2\delta_2$. The symbols α, β, γ, δ are used to denote the peptide chains of which the hæmoglobin molecules are composed and also the genes controlling their structure. The authors propose that "the production of γ-chains is under the control of the same pair of genes which determines the formation of β-chains, once the maturation of the fœtus has reached the point where adult hæmoglobin can be made". Again, in cases of thalassæmia, for example, where there seemed to be a block in the synthesis of β-chains due to a substitution in the chain, "the simplest possible assumption seemed to be that the character or site of the substitution in the β-chain itself determined the nature of the by-product, γ or δ, accumulating in consequence of a block in the metabolic pathway of β-chain synthesis".

Zuelzer and Robinson's hypothesis suggests that the γ- and the δ-peptide chains represent alternative pathways in a synthetic mechanism which in the normal adult results in the production of β-peptide chains. The implication stated is that the alternative pathways to the γ- and δ-chains branch off from the main pathway at, respectively, earlier and later stages of assembly of the peptide chain. A peptide chain will be assembled under control of a β-gene to the stage where it contains n amino-acids, and then completed by the β-gene, if that is normal. However, if there is a mutational alteration in the β-gene (as in hæmoglobin *S*, refs. 2, 3, and 4), then a proportion of unfinished chains of length n will take the alternative pathway controlled by the γ-gene, provided the mutation in β occurs after the branch point.

The elegant work of Dintzis[5] has shown that the two types of peptide chain of rabbit hæmoglobin are made sequentially by stepwise addition beginning at the N-terminus of the chains. Bishop *et al.*[6] had previously indicated that growth of the chain begins at the N-terminus. The size of these growth steps is not clear, but it cannot be larger than a few amino-acids. The same situation presumably exists in man. In that case, and according to Zuelzer and Robinson[1], the peptide chain grows from the N-terminal valine residue until it has reached the nth amino-acid. Growth continues to completion and a normal β-chain results, if the β-gene is normal and the person is an adult. However, in the case of a sickle-cell homozygote, who is abnormal in both his β-genes, a large amount of fœtal hæmoglobin, that is, of γ-chain, is made. In this case[1], growth after the nth amino-acid has been added continues along the alternative pathway under γ-gene control to a finished γ-chain, which is a γ-chain normal in its amino-acid sequence. Here the hypothesis is in difficulties on two counts; first, since we know[4] that the sickle-cell abnormality of the β-gene alters amino-acid number 6 in the β-chain (glutamic acid to valine), the number n, which is supposedly the common sequence between β and γ, must be less than 6. This is a small proportion of the total of 146 amino-acids[7]; nearly 96 per cent of the β- and γ-genes must be separate and must be operating independently, according to Zuelzer and Robinson. Secondly, the N-termini of the β- and γ-peptide chains are reminiscent of one another in sequence, but by no means identical: β-chain = Val. His. Leu. Thr. Pro. Glu. Glu. Lys. Ser....; γ-chain = Gly. His. Phe. Thr. Glu. Glu. Asp. Lys. Ser. ... . Therefore, the number n, the common structural sequence, must be zero. In other words, the whole of the β- and the γ-genes are independent and separate, at least in so far as their function in producing separate and independent β- and γ-polypeptide chains is concerned, in contrast to Zuelzer and Robinson's hypothesis. The idea that the α-, β-, γ- and δ-chains are produced by four genes which are separate has been discussed by several investigators (summarized in ref. 8).

The δ-gene, according to Zuelzer and Robinson[1], takes over at a later stage in synthesis where m amino-acids are already in the chain ($m>n$). From our knowledge of the δ-peptide chain, m must be smaller than 9 amino-acid residues, since Stretton[9] has shown that the β- and δ-chains are probably similar in sequence up to position 9, where instead of a serine residue (β-chain) he finds a threonine. However, sickle-cell homozygotes produce only normal δ-chains and therefore m, the sequence of amino-acids common to β- and δ-chains, must be less than 6 residues. Therefore, at least 96 per cent of β- and δ-genes are separate genes, producing separately controlled peptide chains.

Although the basic concepts of Zuelzer and Robinson's hypothesis are untenable, at least in so far as they can be tested in the human hæmoglobins, it must be admitted that the presence of considerable quantities of fœtal hæmoglobin in their cases of thalassæmia minor is somewhat puzzling. Thalassæmia is a disease occurring in different forms, for which we have at least two hypotheses[10], but perhaps not yet the definitive explanations. However, it seems likely that most of the phenotypes found in the thalassæmias and other hæmoglobinopathies can be explained by the function and malfunctioning, and by the interaction, of the alleles of the α-, β-, γ- and δ-genes at present recognized. These genes are conceived as consisting of four separate genes controlling the synthesis of the four chemically recognizable hæmoglobin chains[8]. Where there is a drastic curtailment or block of the synthesis of one of the peptide chains, it seems to me more fruitful, and usually adequate, to consider consequent increases in the production of other peptide chains as a process of compensation; perhaps this is brought about by a change in the control mechanism which normally regulates the amounts of peptide chain made by each gene.

Note added in proof: The recent work of Schroeder, W. A., *et al.* (*Proc. U.S. Nat. Acad. Sci.*, 47, 811; 1961, and unpublished experiments) on the amino-acid sequences of the γ-peptide chain throws more light on the degree of similarity between the structure of the β- and γ-chains. The differences between them are fairly well spread along their lengths, and therefore regions of similarity are likely to be short and also scattered. In particular, at the C-termini of the β- and γ-chains only the last two amino-acids are the same, -Tyr.His, with dissimilar sequences before these. Therefore, any similarity between the β- and γ-chain genes at the ends corresponding to the C-termini of the peptide chains would have to be confined to a negligibly small proportion of the length of the genes.

[10] Ingram, V. M., and Stretton, A. O. W., *Nature*, **184**, 1903 (1959).

THE basic assumption of our concept[1] of a common metabolic pathway with different end-products depending on the nature or location of substitutions within the hæmoglobin molecule is not the direction in which the synthesis of the polypeptide chain may proceed, but the very premise itself—that the build-up occurs in a stepwise fashion. This is the all-important conclusion which we reached on purely deductive grounds on the basis of the observation that mutations apparently involving β-chain synthesis, for example, the thalassæmias observed by us, could selectively determine whether an excess of γ- or δ-chains is formed.

At the time when we formulated this hypothesis, the concept of a stepwise build-up was a rather radical departure from the then prevalent ideas on the mode of operation of genetic templates. The almost immediate verification of this, our basic premise, by the work of Bishop[2], and that of Dintzis[3], which Ingram quotes, would seem to strengthen rather than weaken our hypothesis. Since no information was available at the time concerning the direction of the build-up, we refrained from making any explicit assumptions on this point. It is true that one can read the implication into our communication that we were suggesting the build-up of the molecule towards, rather than away from, the N-terminal. We were considering the alternative, but had no basis for a choice. We were interested rather in describing our concept in the simplest possible terms, and did not wish to confuse the reader by an alternative which was equally likely but would not materially affect the validity of the basic concept.

We are in complete agreement with Ingram's reasoning but not with his corollary. Now that it is known that the stepwise build-up in the formation of the molecule is at the N-terminal at least for rabbit, and very likely for human, hæmoglobin, it is clear that the correct model must involve convergence toward a common pathway a relatively short distance from the N-terminal, rather than divergence from the common pathway at that same point. It becomes simply a matter of reversing direction now that the necessary information is at hand. It is just as easily conceivable that, given a substitution near the N-terminal, the first few amino-acids are combined into an alternate pattern (for example, γ-chain type), from which the rest of the chain can arise in a normal manner along the common pathway, as it is to assume the opposite type of process. To that extent the hypothesis can now be made explicit. Instead of the 'branching-off point', we must speak of a 'point of convergence'.

Alternate explanations regarding the control of synthesis of hæmoglobin F are not particularly satisfying, as Ingram admits. It is, however, necessary for genetic theory to satisfy not only the structural relationships within the molecule, which no doubt will be clarified one way or the other in the near future, but also a large body of other pertinent observations. The theory of separate γ-genes runs into difficulties with respect to three sets of acts which can be reconciled with our present hypothesis.

One concerns the observations on thalassæmia minor with the stigmata of a β-gene mutation and divergent behaviour with respect to hæmoglobins F and A_2 which formed the basis of our theory[4]. The second is the increasingly well-documented allelism of the high F-gene with known β-genes such as S and C. Evidence from another laboratory will be forthcoming shortly to the effect that the γ-chains of high F carriers are identical in structure with those of normal fœtal hæmoglobin and that the high F in these individuals is evenly distributed throughout the red-cell population. This seems to us grounds for treating γ-chains as mutant β-chains under the control of the β-gene.

The third point is the uneven distribution of fœtal hæmoglobin in the red-cell population in various genetic and acquired disorders, for example, sickle cell anæmia, thalassæmia minor and leukæmia[5,6]. The concentration of hæmoglobin F in a few, rather than in all, cells suggests metabolic influences not under direct genetic control.

We are not attempting to defend at all costs a hypothesis which is, after all, a mere heuristic principle; but we think it is somewhat radical and premature to discard it on the basis of interpreting a relatively minor and peripheral implication as the substance of the argument.

PATHOLOGY

Immunological Study of experimentally induced Extrahepatic Cholestasis

Cohen *et al.*[1] have shown, by means of an immuno-cyto-chemical-fluorescence method, that gamma-globulin is present in the reticulo-endothelial cells of the sinusoids and fibrous tracts of human livers affected by hepatitis of various types and by post-necrotic cirrhosis. To test, in some measure, the unitary concept of liver disease put forward by Shorter *et al.*[2], it was decided to investigate whether similar changes occurred in livers damaged experimentally by the primarily extrinsic method of ligation of the common bile duct.

Rabbits of either sex and no particular breed but of 2 kgm. weight were used for the experiments. Under intravenous nembutal (Abbott) anæsthesia the common bile duct was exposed, ligated near its middle at two points separated by approximately 1 cm. and the intervening part excised. Penicillin powder was dusted over the operation site and the edges of the abdominal wound. Four groups of six animals were so treated and to each group was added a further control animal, which was subjected to exposure of the common bile duct but without ligation and excision of the latter. There were no operation deaths, and, apart from a small stitch abscess in the skin of one animal, no sepsis occurred.

The four groups, including their controls, were killed respectively at 3, 7, 14 and 28 days after operation and with each group a normal animal was also killed. The animals were killed by the intravenous injection of overdoses of nembutal. They were dissected immediately and portions of the right lobe of the liver and of the spleen were removed, frozen rapidly in a dry ice/alcohol mixture at −70° C. and stored at −30° C. while waiting to be sectioned.

Sections 6μ-thick were cut in a cryostat, exposed to a current of warm air (45° C.) for about 10 sec. and then washed for 5 min. in each of three changes of saline which was phosphate-buffered to pH 7·0. Each section was then treated for 30 min. with fluorescein-labelled anti-rabbit globulin of the sheep (Sylvana Chem. Co., New Jersey), washed as before in phosphate-buffered saline and mounted in glycerin. Immunological specificity was controlled by the treatment of two further batches of section either with non-conjugated sheep anti-rabbit globulin (Sylvana

Chem. Co.) or with normal sheep globulin (Wellcome Research Lab.) for 30 min., and, later, after washing in phosphate-buffered saline, with fluorescein-labelled sheep anti-rabbit globulin as before. These sections were also mounted in glycerin.

The sections prepared by both methods were examined immediately by fluorescent microscopy. The results were recorded by the method adopted by Cohen *et al.*, that is, the cells containing gamma-globulin were counted in each of at least three high-power (×40 objective; ×6 eyepiece) fields and the average for one field expressed thus: + = 2–3 cells; ++ = 4–6 cells; +++ = 7–9 cells; and ++++ = 10 or more cells.

In addition, sections from two experimental and both control animals in each group were prepared as above and then stained with hæmatoxylin and eosin; these sections were examined by bright-field microscopy.

Bright-field examination of the livers of the experimental animals in the first group, killed three days after operation, revealed marked accumulation of bile pigment in the hepatic parenchymal cells and bile ductules. Together with this cholestasis there were numerous foci of liver-cell necrosis, generalized enlargement of Kupffer cells, slight histiocytic and fibroblastic reactions in all the portal tracts and patchy proliferation of bile ductules. These changes were unaccompanied by any abnormality of the lobular architecture. The changes found in the second, third and fourth groups, examined 7, 14 and 28 days respectively after operation, were similar in nature and degree, with the exception of the fibroblastic reaction, to those present in the first group. In the later groups the fibroblastic reaction was greater and had also produced short collagenous projections from the portal tracts into the adjacent damaged parenchyma though without significant disturbance of the lobular pattern. In no case was there histological evidence of infection.

Gamma-globulin was found in cells lining the hepatic sinusoids of all the experimental animals of each group, but none was present in the portal tracts or elsewhere in the livers of these animals and there was none at any site in the livers of the control animals. The number of cells containing gamma-globulin increased with increase of the duration of cholestasis. The results are summarized in Table 1. Intracellular gamma-globulin was present in similar amounts in the splenic red pulp of the experimental and control animals of all the groups.

The sinusoidal cells in which the gamma-globulin was found appeared, on histological grounds, to be Kupffer cells. In no cases in the present experiments have these cells shown morphological changes indicating transition to plasma-cells. Although it is impossible to assess whether these cells elaborated or merely took up the gamma-globulin, the latter seems to be more likely in view of the enlargement of the cells, their known phagocytic powers and the lack of histological changes suggesting transition to plasma-cells.

The significance of these findings is obscure. It must be mentioned, however, that Havens[3] has conjectured that some forms of liver disease may be initiated or perpetuated by the formation of antibodies to the products of liver-cell necrosis, but whether this is the explanation of the liver damage which follows the experimental induction of extra-hepatic cholestasis must await the results of further investigations. On the whole, in agreement with Cohen *et al.*, it seems doubtful that the increase in hepatic gamma-globulin found in some diseases of the liver indicates the presence of any immunological process.

Table 1. CELLS CONTAINING GAMMA-GLOBULIN IN THE LIVER IN EXPERIMENTALLY PRODUCED EXTRA-HEPATIC CHOLESTASIS

Time interval in days	Groups	No. of animals	Liver	
			Cells containing gamma-globulin in portal tracts	Cells containing gamma-globulin lining sinusoids
3	Animals with ligated bile ducts	6	0	+
	Control animals	2	0	0
7	Animals with ligated bile ducts	6	0	+ to ++
	Control animals	2	0	0
14	Animals with ligated bile ducts	6	0	+ to +++
	Control animals	2	0	0
28	Animals with ligated bile ducts	6	0	+++ to +++
	Control animals	2	0	0

Finally, it seems that these results do not oppose a unitary concept of liver disease as a whole, since a change found in a wide variety of diseases of the liver, namely, the appearance of gamma-globulin in reticulo-endothelial cells lining sinusoids, has also occurred in uncomplicated experimentally produced extra-hepatic cholestasis.

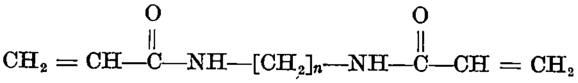
N,N′-Alkylene-*bis*(Acrylamides), N-(Acrylamidomethyl)-3-Halopropionamides and Related Compounds: a New Series of Anti-tumour Agents

THE chemical, biological and clinical aspects of the 'alkylating agents' as anti-tumour agents have been reviewed thoroughly[1,2]. The available data indicate that at least two minimal requirements are necessary for possible alkylating agents[2]: (1) Such compounds must either have a certain chemical reactivity, or be converted *in vivo* to structures that do; (2) although polyfunctionality is not a rigid requirement for activity, the most active alkylating agents are polyfunctional. Functional groups with chemical reactivity are usually defined as those able to react with nucleophilic groups such as amino and mercapto, and the anions of carboxylic and phosphoric acids.

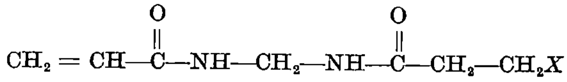
In the course of syntheses of compounds with potential anti-tumour activity, N,N′-methylene*bis*-acrylamide[3] [I, $n = 1$] was submitted for screening and found to inhibit markedly the growth of two transplanted mouse tumours (specific details later in this communication). Chemically, N,N′-methylene*bis*acrylamide fulfils the requirements for an active alkylating agent, since both α,β-unsaturated linkages can easily add mercaptans or amines[4]. Inasmuch as this structure represented a new type of anti-tumour agent, an effort was undertaken to define more precisely the structural characteristics necessary for anti-tumour activity. As a result, compounds of three related though distinct structure types were found to be active against at least one transplanted mouse tumour. The general structures are as follows:



$$CH_2=CH-\overset{\overset{O}{\|}}{C}-NH-[CH_2]_n-NH-\overset{\overset{O}{\|}}{C}-CH=CH_2$$

I

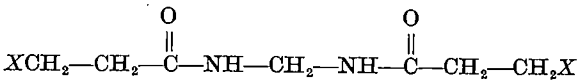
$n = 1,2,3,6,7$



$$CH_2=CH-\overset{\overset{O}{\|}}{C}-NH-CH_2-NH-\overset{\overset{O}{\|}}{C}-CH_2-CH_2X$$

II

$X = Cl,Br,I$



$$XCH_2-CH_2-\overset{\overset{O}{\|}}{C}-NH-CH_2-NH-\overset{\overset{O}{\|}}{C}-CH_2-CH_2X$$

III

$X = Br,I$

Except for the compound with $n = 1$, the compounds of type I were obtained by the action of acrylyl chloride or acrylic anhydride on the appropriate α,ω-alkylenediamine. The compound where $n = 1$ was obtained by the action of formaldehyde on two moles of acrylamide[3]. The compounds of type II were obtained by the action of N-(hydroxymethyl)acrylamide on the appropriate 3-halopropionamide in the presence of an acidic catalyst. The compounds of type III were obtained by the action of formaldehyde on two moles of the appropriate 3-halopropionamide.

Compounds of type I wherein one or both acrylamide residues were replaced by methacrylamide (one) or β,γ-buteneamide residues (one and two) were also found to possess anti-tumour activity, while crotonamide, cinnamamide and sorbamide residues gave inactive compounds. The full chemical details on all the above compounds, as well as on numerous other inactive compounds, will be published elsewhere.

In our Laboratories, compounds are screened for anti-tumour activity against a spectrum of three transplanted tumours in *C3H* mice: sarcoma 180, 6*C3HED* lymphosarcoma, and *C3H* mammary adenocarcinoma. The details of the screening procedure have been published[5]. All the active compounds described before inhibited the growth of the *C3H* mammary adenocarcinoma. In addition, N,N′-methylene*bis*acrylamide inhibited the sarcoma 180, and N,N′-ethylene*bis*acrylamide [I, $n = 2$] inhibited the 6*C3HED* lymphosarcoma. One compound, N-(acrylamidomethyl)-3-bromopropionamide [II, X = Br], inhibited all three screening tumours. Evaluation studies showed that this compound was effective against all three tumours by oral administration as well as by intraperitoneal injection. It prolonged significantly the survival-time of mice bearing the transplanted *C3H* mammary adenocarcinoma, but was ineffective against 'spontaneous' mammary adenocarcinomas. In common with the alkylating agents, N-(acrylamidomethyl)-3-bromopropionamide acts as a bone marrow depressant[6]. Detailed results of the screening and evaluation studies will be published elsewhere.

N-(Acrylamidomethyl)-3-bromopropionamide is now undergoing limited preliminary clinical trials.

Two Phycomycetes isolated from Subcutaneous Phycomycosis in Uganda

In 1956, Lie Kian Joe *et al.*[1] reported two cases of a curious subcutaneous granuloma in children in Indonesia. The tissues showed a characteristic histological picture in the midst of which lay fungus filaments with occasional septa. From one case they isolated many colonies of a phycomycete, *Basidiobolus*, not hitherto known to infect mammals. Later this group of workers has reported three more cases[2]; *Basidiobolus* was isolated from two of them and an unidentified phycomycete from the third. A sixth case, probably infected in Indonesia, has been recognized by biopsy examination in England[3].

The general term 'phycomycosis' was suggested for diseases caused by members of the Phycomyces[4] to avoid the restricted connotation of mucormycosis and to cover cases in which a phycomycete was demonstrated by histology or culture, but closer identification was not possible.

A chronic progressive subcutaneous granuloma affecting only children and producing a characteristic picture on biopsy examination has been recognized in Uganda for many years[5]. It is locally known as 'creeping granuloma' and, though never proved, it has been regarded as most likely due to some helminthic infection largely because of the small 'tunnels' in the sections and the heavy infiltration of eosinophil cells around them. Jelliffe *et al.*[6], however, concluded that their patient with 'creeping granuloma' was suffering from a mycotic infection which they recognized as the subcutaneous phycomycosis of Lie Kian Joe.

About the same time, and unaware of the previous work, I also had come to the conclusion from a study of a series of biopsies that 'creeping granuloma' was a mycotic infection, and was afterwards able to isolate *Basidiobolus ranarum* from the next case presenting with this condition. Prof. Lie has seen the biopsy from this patient and agrees that the picture is identical with that of the Indonesian cases. The identity of the 'creeping granuloma' of Uganda and the subcutaneous phycomycosis of Indonesia therefore seems clear.

In connexion with the isolation of *Basidiobolus* in Uganda (the first from human tissue outside Indonesia), it is of great interest to note that the report referred to in ref. 5 is not accurate where it says a fungus had been sought in one case without result. A fungus was isolated from this case and it was identified by the Mycological Reference Laboratory at the London School of Hygiene as a member of the *Entomophthora* group, but as no connexion was then known between any human disease and such a phycomycete, it was considered of no significance. The records at that Laboratory have been consulted and confirm that the fungus was a phycomycete of the order Entomophthorales, probably an *Entomophthora* but certainly not a *Basidiobolus*. The evidence both from Indonesia and Uganda thus suggests that subcutaneous phycomycosis may be caused by more than one kind of phycomycete.

There is as yet no evidence either from Indonesia or Uganda of the way in which a fungus such as *Basidiobolus* is transferred from its normal habitat in the intestinal contents of frogs and beetles to the subcutaneous tissue of children, and this is now being investigated.

BIOLOGY

Correlative Inhibition of Formation of Chlorophyll in the Leaves of Etiolated Pea Plants

Seventeen-day-old pea plants (*Pisum sativum* L., variety Přebohatý) grown in the dark were decapitated above the different nodes as illustrated by horizontal bars in Fig. 1. The decapitated plants and the isolated sections of the stems were placed in a window of the laboratory, left there overnight and on the next day exposed to daylight. After 24 hr. the chlorophyll formation in the individual organs was visually evaluated by means of a standard colour scale.

Fig. 1 shows that in intact control plants (*a*) the young leaves of the apex (*Aa*) and its region of elongation had become intensively green. The isolated stem tips (*Ab* ; *Af*) had formed chlorophyll to a lesser extent. In the decapitated plants chlorophyll formation took place mainly in the morphologically highest organ (*L2b* ; *L1c* ; *S2d*). Such organs and even the organs on isolated stem sections (*L2f*; *L1f*) usually formed more chlorophyll than the corresponding organs on intact plants (*L2a*; *L1a*) or on stem sections with the stem tip intact (*L2d*; *L1d*). The experiment clearly shows that in leaves chlorophyll formation is inhibited even in the absence of the apex if there is a morphologically higher, that is, younger node present.

In the presence of the basal parts, on the contrary, chlorophyll formation (compare *S2d* with *S2f* or *Ae* with *Af*) is stimulated. Individual organs differ in their capability to form chlorophyll according to their age if the inhibiting apical parts are removed as may be seen by comparing *L2b*, *L1c*, *S2d* and *S1e*. The fact that inhibition in the presence of apical parts is expressed not only in the control of the growth of lateral buds but also in the control of chlorophyll formation in the leaves and scales stresses the necessity to look on the plant as a well-co-ordinated whole[1,2,8]. The present concept of apical dominance[8] emphasizes the importance of the stem tip controlling directly or indirectly the growth of lateral buds. If the totality of the plant is to be taken into consideration it seems necessary to extend this concept to the active function of the transport system[3-5,7] in the theory of correlations until now somewhat underestimated.

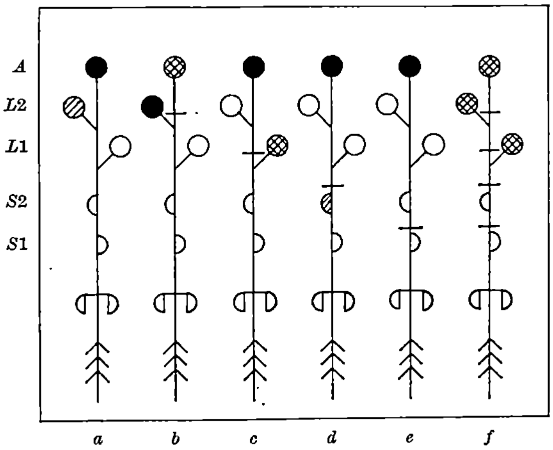

Fig. 1. Chlorophyll formation in the leaves and scales of etiolated plants and isolated stem sections of *Pisum sativum* after exposure to daylight for 1 day

In a normal etiolated pea plant it is the metabolic activity of the apex, driving the energy-requiring processes, that maintains the material, metabolic and electric gradients. These gradients in turn render possible a continuous flow of material to the apex, acting, with respect to this flow, as a metabolic sink or a centre of attraction. In such a process, positive[7] and negative[6] feedback mechanisms take part; auxins, gibberellins, kinetins and inhibitors together with their precursors represent probably important components of such systems.

If the transport, at least of some of the necessary material, by the conducting system is an active process, the 'pull of material'[5] by the conductive system continues even after the removal of the stem tip, so that one can speak about a 'memory' or 'inertia' of the system. This state probably has a more-or-less transient character; but it is supposed to play a decisive part in the first phases following the removal of the apex. Then, in analogy to a suddenly closed pipe line with an excessive pressure arising, the pulled material starts to flow to organs that were not reached before, partly due to resistances encountered.

The differences depending on age in chlorophyll formation by the leaves and scales are probably due to differences in such resistances of metabolic or mechanical character. It is assumed that similar relations participate in a variety of other phenomena studied by experimental morphology, such as the differences in mass production by the marginal buds of *Bryophyllum crenatum* leaves[2] or even the classical case of the cotyledonary bud inhibited by its cotyledon[2].

Apical dominance and similar phenomena are considered as special cases of metabolic correlations representing the basic principle of the totality of plant organism.

I wish to express my thanks to Prof. Rudolf Dostál for stimulating discussion.

Flower Initiation in the Carnation in Response to Photoperiod

In 1932, Laurie and Poesch[1] reported that for glasshouse carnation an increase in photoperiod during the winter months led to earlier production of flowers in the spring. There have been a number of similar reports since, but views have differed as to whether photoperiod affects the time of flower initiation or only the rate of subsequent development of the flower. Post[2] and more recently Rünger[3] have claimed that only the latter stage of development is affected. Blake[4], however, working in the laboratories here, demonstrated an effect on flower initiation such that plants grown in short days of 8 hr. had more leaves below the flower than plants grown in long days where an additional 9 hr. of illumination was given. The object of the present communication is to report results from three glasshouse experiments which show unequivocally that time of flower initiation in carnation is affected by photoperiod and that this effect can occur independently of the total radiation received by the plant.

In experiments 1 and 2, plants were grown from normal shoot cuttings. These were cut back about one month after planting and one axillary shoot was allowed to develop. In experiment 3, plants were grown from 'leaf-bud cuttings' comprising an axillary bud, its subtending leaf and a small portion of stem. The variety White Sim was used throughout. The basic treatment was 8 hr. of natural daylight (short day). In the other two treatments this was supplemented by 2 hr. of light from 'daylight' fluorescent tubes plus tungsten filament lamps, given either as 1 hr. at either end of the day (extended day) or as 2 hr. at the middle of the dark period (interrupted night). In each of the three experiments sampling of the plants and dissection of their apices showed that flowers had been initiated in the 'interrupted night' treatment, while plants in the other treatments were still vegetative (Table 1).

Table 1

Experiment No.	Date of planting	Date of sampling	No. of plants with flower primordia out of six sampled		
			Short day	Extended day	Interrupted night
1	28.1.60	26. 5.60	None	None	5
2	15.6.60	12.10.60	None	None	6
3	23.4.60	6.10.60	None	None	3

Further treatments in the experiments quoted, and further experiments now in progress here indicate that a number of factors can interact with photoperiod in effects on flower initiation. An understanding of these factors is desirable in considering any possible applications of photoperiodic treatments to the growing of carnations for cut flowers.

We wish to express our appreciation to the Agricultural Research Council, which has made a grant to support this work.

Measurement of Leaf Colour

Leaf colour is a valuable index of nutrient status in flowering plants. Yellowing of the leaves is associated with deficiencies of nitrogen, magnesium, iron, manganese, zinc and molybdenum in many species.

The severity of leaf chlorosis has been recorded by subjective description, by colour photography and by estimation of the chlorophyll content. Chlorophyll estimations yield unambiguous results and have proved most satisfactory in experiments requiring a high degree of accuracy.

In many investigations it is desirable to measure the changes in colour which occur during maturation of the leaf. Chlorophyll estimations involve the destruction of the leaf, and, in consequence, large-scale experiments must be carried out in order to provide an adequate replication in each sample of leaves. As an alternative to this rather laborious procedure, a system of colour matching suitable for attached leaves has been adopted in recent experiments on lime-induced chlorosis, carried out at Sheffield.

A comparator has been made. The colours were prepared by mixing oil paints, which were applied to squares of absorbent paper (thick filter paper is suitable). The colours were arranged in series and matched against the Ridgway[1] colour standards (Table 1). Through the colour series there is a regular change in spectral composition. In order to match chlorotic leaves more easily (they are often bleached in addition to being yellow in colour) the colours at the yellow end of the comparator are of lower intensity.

Colour matching is carried out under standard conditions of white lighting provided by a Siemens-Ediswan Daylight Blue 60-W. lamp. Where leaves show an intervenal chlorosis, the colour matched is that of the intervenal areas.

The error involved in matching leaf colours varies according to the characteristics of the leaf. Species with waxy or glossy leaves are the most difficult subjects. In *Lathyrus montanus* and *Betonica officinalis*, the leaves of which have a matt surface, the error was found not to exceed 5 per cent in the 10–25 range of the colour series and 3 per cent in the 26–33 range.

Even in the standardized environment of a growth cabinet, the rates of leaf appearance in a population of seedlings germinated at the same time are not synchronous. For this reason, colour-values determined at fixed intervals of time after germination are not comparable. Trials have shown, however, that development of colour in successive leaves can be measured satisfactorily if the timing of the determinations is based on a biological unit of time. The unit is that occurring between the appearance of two successive leaves at the same growing point, that is, in each seedling, the colour of each foliage leaf is measured when its successor first appears and afterwards, at intervals determined by the appearance of successive leaves, at the same growing point. Provided that sufficient records are obtained and the behaviour of the seedlings is fairly uniform with respect to leaf colour, a series of curves or histograms may be constructed to represent the development of leaf colour during the seedling phase (Fig. 1). Where the primary shoot is non-persistent, being replaced by one or more secondary shoots soon after germination, the source of comparable data is limited. The system of colour-matching is unsuitable for grasses because growth is not monopodial and the leaf is not a unit of limited growth as it is in a dicotyledon.

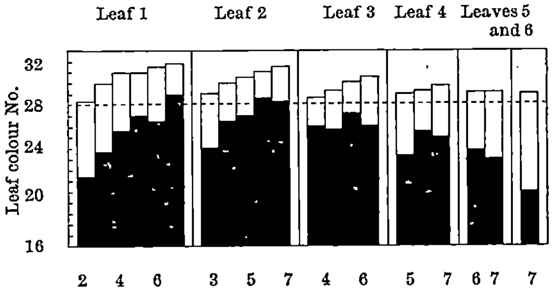

Fig. 1. Leaf colour measurements to show the onset of a permanent lime-induced chlorosis in seedlings of *Betonica officinalis*. Critical boundary line at colour number 28. □, On nutrient-sufficient brown earth; ■, on calcareous soil.

Table 1. Colour Series used in the Leaf Colour Comparator. Inset is the Range sufficient for most Species

Colour No.	Ridgway colour No.	Name of colour
1 2 3	23*B*	Pale lemon yellow
4 5 6	25*B*	Light greenish yellow
7 8	25*I*	Oil yellow
9	27*I*	Javel green
10		
11 12	29*I*	Cosse green
13 14 15	29*K*	Lettuce green
16 17 18	31*I*	Yellow green
19 20 21	31*K*	Parrot green
22 23	31*M*	Cedar green
24 25 26 27 28	33*I*	Scheele's green
29 30 31 32	34*K*	Grass green
33		
34 35	35*K*	Meadow green
36 37 38	35*M*	Antique green
39	37*M*	Diamine green
40 41	39*M*	Anthracine green
42	41*M*	Myrtle green

In comparative work on lime-induced chlorosis it has been found possible to construct, for each species, a critical boundary-line above which lie the colour development curves from control seedlings on a non-calcareous soil having sufficient nutrients. Values which fall below the boundary indicate some degree of chlorosis. The position of the boundary line varies according to the species, being at 25–26 in *Rumex acetosa*, 26–27 in *Betonica officinalis* and 30–31 in *Trifolium medium*.

Interspecific comparisons may be made in seedlings by examining the timing and magnitude of disparencies between the colour data for leaves of the experimental and control plants. A convenient method of summarizing this type of information is illustrated in Fig. 2.

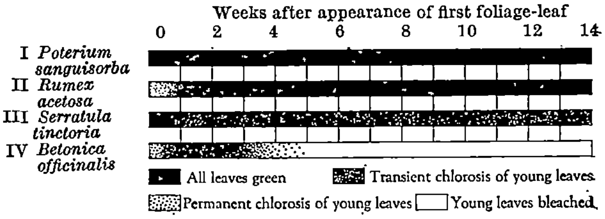

Fig. 2. The pattern of colour development in seedlings of four species growing on a calcareous soil. I, No chlorosis; II, transitory chlorosis; III, persistent, non-progressive chlorosis; IV, progressive chlorosis

The method is sensitive to the blue-leaf effects which are associated with an abundant supply of nitrogen. The comparator may not be used to follow the changes in colour in senescent leaves, as these are essentially changes in intensity and may be paralleled by the accumulation of masking piments.

Non-Lethal Pathological Infection of Roots

Rovira and Bowen[1] reported reduction in root elongation and in root-hair development following the addition of pasture soil suspension to seedlings of clover, tomato, *Phalaris tuberosa* and *Pinus radiata* raised in sterile agar or sand culture. They suggested the possibility of a complex interaction between plants and micro-organisms. Since there was no observable effect on the plant tops in their experiments, the reduced absorbing surface of the roots was apparently

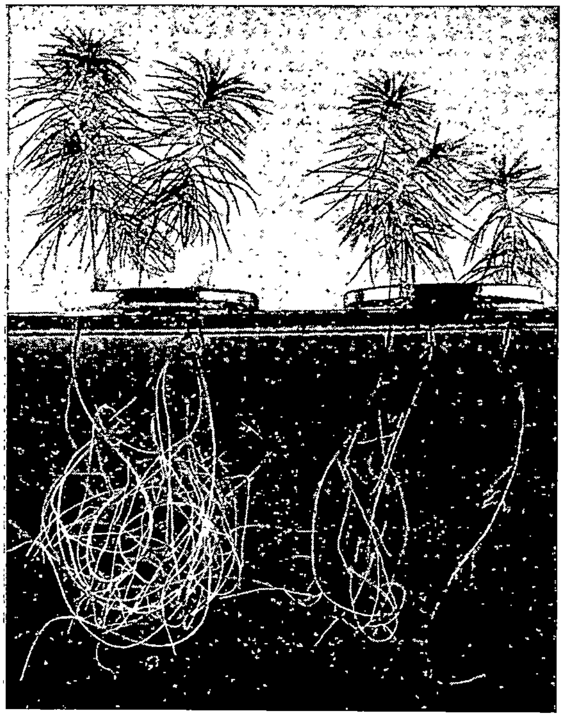

Fig. 1. Uninoculated control seedlings of *P. radiata* on left; plants on right are taken from liquid culture jar inoculated with *Phytophthora* sp. three months before

offset by the 'luxury' amounts of plant nutrients used.

While continuing investigations on a disease of *P. radiata* caused by *Phytophthora* spp. in New Zealand[2,3], some inoculation results were obtained in which many infected roots were drastically retarded without being killed. While the phenomenon recorded by Rovira and Bowen may have been similar to the stunting of roots and shoots without actual infection as reported by Kerr[4], it may have been due to the condition described here.

Newly germinated seedlings of *P. radiata* were grown in aerated culture solution for three months in a glasshouse. They were then inoculated by adding zoospores of a *Phytophthora* sp. which is widespread in pumice soil supporting a large 30–35-year-old plantation of *P. radiata*. Three weeks after inoculation, roots were found to be infected, being pale brown in colour and covered with mycelium and large numbers of sporangia. After a further three weeks many of the infected primary and secondary roots were dead, particularly in the distal portions of the root systems, but many others had resumed apical growth or were producing new lateral roots through infected cortical tissues. New root growth was very restricted by comparison with uninoculated check plants. After a further six weeks new root growth was still sparse and top growth of living plants was markedly depressed (Fig. 1). Shoot length was reduced by a third and the length of scale leaf by a fifth of that in the controls. The non-lethal infection and stunting of roots was obtained in aerated and non-aerated nutrient culture solutions or in tap water replacing the original culture solution. The pathogen was re-isolated from portions of retarded root.

Microtome sections of retarded roots showed that mycelium was confined to the cortex, being intracellular and reaching, but not penetrating, the endodermis. In dead roots mycelium had invaded all tissues, with occasional oospores occurring in the vascular cylinder.

Similar results were obtained in a further test with the same and other *Phytophthora* spp., including *P. cinnamomi* and *P. cactorum*. In some experiments infection resulted in death of complete root systems.

A significant feature of the results is that in the absence of control plants many of the diseased root systems would pass as healthy, the pale brown roots with infected cortical tissues being outwardly similar to roots undergoing normal suberization. In the field, where there are no controls to give a measure of root stunting, it is common to find rootlets with dark cortical tissues and white vascular cylinders which are still functional, judging by the possession of white elongating root tips.

Phytophthora spp. have been found to be widespread in New Zealand, in cultivated soil, exotic pine plantations and indigenous forests. If they and other soil fungi, in addition to being active pathogens on some plants, are affecting less-susceptible hosts in a manner similar to that described here, they must be regarded as constituting an important but not easily recognized biotic factor of the environment. In this role they could, for example, be of significance in some of the puzzling decline diseases in which there is an apparent lack of primary symptoms. They could also be predisposing agents in connexion with insect or fungus attack on upper parts of plants where low moisture content is a governing factor. By affecting host vigour they could influence ecological succession in natural plant communities.

Wettability and the Capture, Carriage and Deposition of Particles by Raindrops

During rain the particulate matter of the atmosphere is washed to the ground, and it has been suggested that the wettability of the particles affects the efficiency with which they are picked up by the falling droplets. The rain-wash of fungal spores which are not easily wetted has been reported, however, by Gregory[1] and Hirst[2]. It was therefore decided to investigate the effect of surface wettability on the manner in which fungal spores are captured, carried and deposited by water droplets. The investigation was carried out with the simplest of apparatus and by direct observation under the microscope.

Capture and carriage. Water droplets approximately 2 mm. in diameter were caused to fall distances between 10 cm. and 25 cm. so that they then swept the conidiophores of *Verticillium alboatrum* or *Penicillium chrysogenum* before being caught in a mixture of oil and 'Vaseline'.

Droplets which swept *Verticillium* conidiophores invariably contained spores which exhibited Brownian motion within the droplet. No spores were ever observed within the droplets which had swept *Penicillium* conidiophores; but the spores were always observed on the surface of the droplet and most frequently at the boundary where the droplet rested on the oil and 'Vaseline' mixture. Evidently the readily wettable *Verticillium* spores enter the droplets with ease, whereas with the *Penicillium* spores, with their water-repellent surfaces and under the conditions of these experiments, impact velocities between spores and droplets were too low to overcome the interfacial energy at the surface of the droplets.

Since electrostatic charges have been shown to occur on raindrops by Chalmers[3] and on spores in air by Gregory[4], the possibility of an electrostatic attachment between water droplets and spores with water-repellent surfaces was investigated.

A mass of *Penicillium* spores held on the point of a steel needle was brought into contact with a water droplet produced at the tip of a hypodermic needle and subsequent events observed under the microscope. With both needles connected to earth, that with the spores was slowly moved away from the droplet. As this was done, it was observed that the part of the droplet in contact with the spores became drawn out, until finally, when contact ceased, the droplet assumed its original shape and a number of spores was left adhering to its surface.

Since both droplet and spores were earthed, it must be concluded that despite the water repellency of the spore surface, the spores were held to the droplet surface by molecular adhesion.

The manner in which fungal spores are captured and carried by rain or spray droplets is influenced by the wettability of the spore surface. The readily wettable spores of *Cephalosporium, Fusarium, Verticillium* and *Pullularia* enter droplets with ease and are carried within. At low impact velocities the 'non-wettable' spores of *Aspergillus*, *Cladosporium* and *Penicillium* are captured by adhering to the surface of the droplet.

Deposition of spores on water-repellent surfaces. Since most vegetation has water-repellent surfaces, it was decided to investigate whether surface wettability affected the deposition of spores by water droplets. In an initial experiment a microscope slide was covered on one surface with a mixture of 'Vaseline' and paraffin wax. A water droplet with its surface densely covered with 'non-wettable' *Penicillium* spores was placed at one end on the prepared surface, and the slide inclined and sharply tapped so that the droplet ran over it. As the droplet moved, most of the spores became attached to the hydrophobic surface and were visible to the unaided eye as a linear 'stain' along the course taken by the droplet. When the procedure was repeated with wettable *Verticillium* spores, and the slide examined under the microscope, no spores were seen in the track over which the droplet moved. When the experiment was repeated using plant leaves and the spores of other fungi, similar results were obtained.

It may be concluded, therefore, that when a droplet carrying spores falls on and moves over a hydrophobic plant surface, any 'non-wettable' spores brought into contact with the surface will tend to be deposited to the rear of the moving droplet, whereas wettable spores will either be washed away or deposited where the droplet comes to rest. During rain, the process is complicated by the splash-dispersal mechanism described by Gregory *et al.*[5] and the fact that through contact with water the wettability of a hydrophobic surface increases (Adam[6]).

Water droplets falling on hydrophobic leaf surfaces do not form a continuous film, but, to quote an expression of Adam, "pearl away in beads". It was observed that when a succession of droplets from a point source fell on a blade of grass, the beads did not run along the axis of the blade but 'pearled' off the edges, frequently alighting on an adjacent blade. This pearling away of water in beads from hydrophobic plant surfaces may in itself act as a spore dispersion mechanism distinct from the splash mechanism of Gregory *et al.*[5].

While it has not been investigated, in the removal of a radioactive dust cloud by rain, a 'non-wettable' fraction might tend to be deposited and retained on the surfaces of vegetation.

Taxonomy of *Xanthomonas* and *Pseudomonas*

Application of computers to problems of bacterial taxonomy has been suggested by Sneath[1], who described a method for handling large quantities of taxonomic data by an electronic computer. By this type of analysis, an outline of classification based on equally weighted features is obtained.

Hill[2] carried out an electro-taxonomic analysis of the *Staphylococci* and determined *Staphylococcus aureus*, *S. saprophyticus*, and *S. roseus* to be natural groups, whereas *S. lactis* and *S. afermentans* were not, since individual strains of these 'species' proved to be as different from each other as from the previous species. Other taxonomic studies involving the use of a computer[3] have yielded equally interesting results.

Work on the classification and taxonomy of the *Pseudomonas*, *Achromobacter*, *Flavobacterium* groups using the IBM 650 magnetic drum computer is being carried on in our laboratory[4,5]. The method clearly indicates generic and supra-generic groupings and there are indications, from our results and from others reported[6,7], that the genus-level may lie approximately at 60 per cent and the species-level at 75 per cent *S* ('similarity value'), meaning that organisms of the same genus will share about 60 per cent of their characters and strains will share 75 per cent or more of their characters.

Since *Xanthomonas* is distinguished from *Pseudomonas* by production of a yellow insoluble pigment and by plant pathogenicity, and since some *Pseudomonas* are plant pathogens, we became interested in applying the Adansonian method in an analysis of representatives of these groups to determine whether

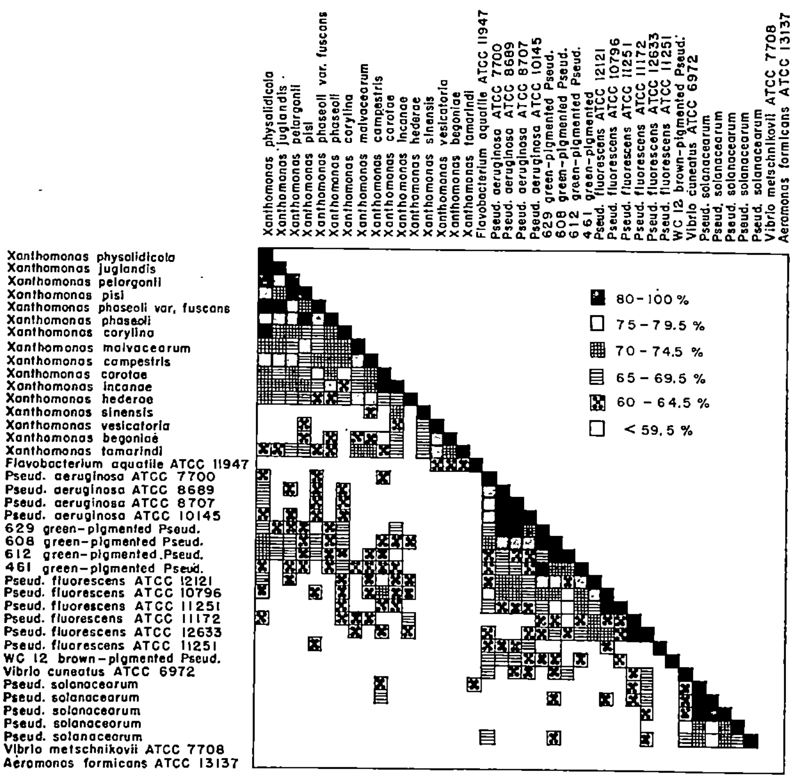

Fig. 1. Full table of S-values obtained from the analysis of forty representative strains, predominantly *Xanthomonas* and *Pseudomonas*

the separation of *Xanthomonas* from *Pseudomonas* is real or artificial (that is, taxonomic or determinative).

Some well-defined species of *Xanthomonas*, strains of *Pseudomonas solanacearum* which had been isolated from widely different geographical sources, and a number of named and freshly isolated *Pseudomonas* species were studied. All strains were tested, using standard bacteriological methods[8], in our laboratory and the 134 characteristics or 'states' obtained for each culture were punched on data cards. Calculations of S-values were performed by machine. The full S-table results are shown in Fig. 1.

It appears that three groupings were obtained: *Xanthomonas physalidicola* to *Flavobacterium aquatile*: *Pseudomonas aeruginosa* ATCC 7700 to *Vibrio cuneatus*; and the *Pseudomonas solanacearum* strains. *Vibrio metschnikovii* and *Aeromonas formicans* fall completely outside the *Pseudomonas–Xanthomonas* groups, in accord with results of other analyses[5].

The *Xanthomonas* species fall very clearly into two related groups which we have called *Xanthomonas* I and *Xanthomonas* II, for convenience. *Xanthomonas* II, the small group, contains only four species: *X. sinensis*; *X. vesicatoria*; *X. begoniae*; and *X. tamarindi*. All other species of *Xanthomonas* fall into Type I. However, within Type I, there is a small, tight clustering of the species *X. physalidicola* to *X. phaseoli*, which are so clearly related that they seem to form a 'taxonomic' species (intra-group $S = 78$ per cent). The five *Pseudomonas solanacearum* strains form a closely related group, quite distinct from *Xanthomonas* types, and probably constitute a true taxonomic species (intra-$S = 75$ per cent).

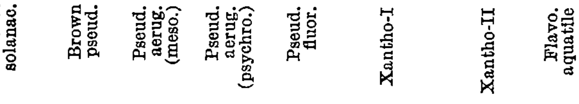

Fig. 2. Diagrammatic representation of inter- and intra-group S-values indicating group relationships

The fluorescent *Pseudomonas* form a large homogeneous group (intra-$S = 69$ per cent) within which three sub-groups can be delineated: a *Pseudomonas fluorescens* group and two *Pseudomonas aeruginosa*-like groups, one psychrophilic (461 to 629), consisting of organisms from marine sources and the other mesophilic, including all the ATCC *P. aeruginosa* cultures.

The two *P. aeruginosa* groups are so closely related (inter-$S = 74$ per cent) and individually so homogeneous (intra-$S = 75$ per cent and 85 per cent, respectively) that they could represent a single species with two varieties.

The maximum values for the inter-group S-values are shown in Fig. 2, the groups having been arranged according to the computed inter- and intra-S-values. It can be noted that *Xanthomonas* links with the *aeruginosa–fluorescens* block by a group relationship between the latter and *Xanthomonas* I, at a level close to the possible genus-level. *Xanthomonas* II is closely related to *Xanthomonas* I, but not to the principal *Pseudomonas* group. Indeed, it is interesting to note that *Xanthomonas* II has a nearly generic relationship with the ATCC *Flavobacterium aquatile*, which may not, however, be a *Flavobacterium*, since it has polar flagella.

As shown in Fig. 2, the *Pseudomonas solanacearum* species, which themselves produce a brown pigment, are linked to the *Pseudomonas* group through relationship with a sea-water-requiring brown-pigmented *Pseudomonas* species, but differ as much, or more, from the other *Pseudomonas* tested, as did the *Xanthomonas* species.

A more complete presentation of these results, with a discussion of the characteristics separating the groups, will be published in full elsewhere.

The *Xanthomonas* species were supplied by Dr. M. P. Starr, Department of Bacteriology, University of California, Davis, and the *Pseudomonas solanacearum* isolates by Dr. A. Kelman, Plant Pathology Department, North Carolina State College, Raleigh. The named strains of *Pseudomonas aeruginosa*, *Pseudomonas fluorescens*, *Vibrio metschnikovii*, *Aeromonas formicans* and *Flavobacterium aquatile* were obtained from the American Type Culture Collection, Washington, D.C. Other pseudomonads were freshly isolated in our laboratory from marine sources.

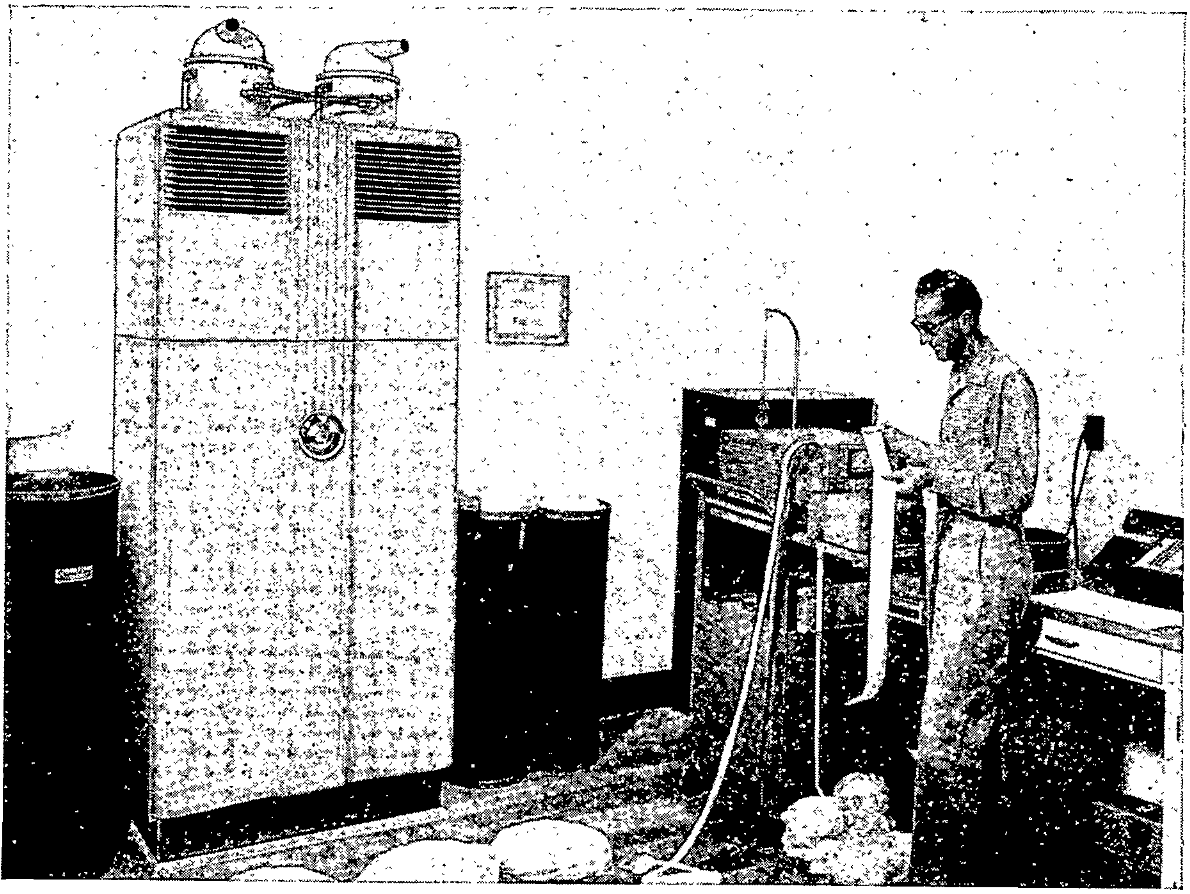
CARLYLE

LABORATORY CONDITIONERS



give you 'PRECISION CONTROL' of temperature and humidity

No one knows better than you that varying air temperatures and humidity can affect the properties of materials, and the accuracy of instruments and experimental results. These problems can be overcome by the installation of a Carlyle Laboratory Air Conditioner. This completely self-contained unit—specially designed for laboratory work—will ensure year round control of temperature and humidity to within ±1°F and ±1½% R.H. The Carlyle Unit is the result of years of specialised experience in all phases of atmosphere control involving application of air conditioning and refrigeration to industrial plants and processes.

Capacities from 29,000 to 80,000 Btu/hr

Larger capacities are also available on special order. We shall be glad to co-operate with organisations in recommending the unit most suitable for their purpose.

Effects of Kinetin and Indole-3-acetic Acid on Multiplication Rates of *Paramecium*

Kinetin (6-furfuryl aminopurine) is known to cause division in certain plant cells which could not otherwise divide[1]. But other cases are reported in which the rate of cell division is decreased after its application, for example, those of De Ropp[2], Kemp *et al.*[3], Pilet *et al.*[4], and Ham *et al.*[5]. How this substance affects the rate of division of animal cells is a question of interest. In a recent report[6], Guttman and Back re-analysed data and repeated experiments in which they had previously[7] found that kinetin causes an increase in the rate of division of *Paramecium caudatum* when added in low doses to the culture medium. Their later work[6] indicated that stimulation of cell division was present, but on a lower level than that previously reported. Coincident with the appearance of the second report of Guttman and Back, we reported elsewhere[8] the results of experiments in which kinetin, when used at the same concentrations and under similar conditions, was found to be inhibitory to division of *P. caudatum*.

Table 1 shows the results of a series of experiments in which comparisons were made between controls and treated *Paramecia* which were immediate descendants of one individual of a clone. In every series, there was inhibition of division at a significant level of confidence in kinetin-treated *Paramecia* as compared with untreated controls.

A smaller series of comparisons was made between rates of division in *Paramecia* treated with kinetin plus indole-3-acetic acid (IAA), and untreated controls. The results are given in Table 1. The results show that IAA appears to reverse the inhibition of division produced by 0·5 p.p.m. kinetin, and to counteract the severity of the inhibition produced by 1·0 and 1·5 p.p.m. kinetin. Antagonism between kinetin and IAA has been found in other experiments, for example, those of Wickson and Thimann[9] in lateral bud development.

Table 1. Mean Numbers of Divisions per 24-hr. Period of *Paramecia* treated with Kinetin (K) alone or in Combination with Indole-3-acetic Acid, as compared with Untreated Controls

No. of 24-hr. comparisons	Control	*S.E.*	Treatment solution (p.p.m.)			*t* value	Level of significance
			0·5 K.	1·0 K.	1·5 K.		
64	0·843	0·47	0·742			1·7	0·1
60	0·850	0·51		0·650		2·99	0·01
61	0·819	0·49			0·606	3·31	0·01
			0·5 K. +2 IAA	1·0 K. +2 IAA	1·5 K. +2 IAA		
41	0·607	0·48	0·607				
42	0·619	0·48		0·548		0·939	0·35
41	0·610	0·23			0·512	1·271	0·25

The method of treatment and handling of materials in our experiments were the same as those described by Guttman and Back[6], except that the nutrient medium we used was a snail-egg extract which had been filtered, sterilized, and adjusted to *p*H 6·8, rather than hay infusion. The ambient medium was changed every 24 hr., whether the *Paramecium* had divided or not. Cultures were maintained in depression slides at 25 ± 2° C. The kinetin used was obtained from Nutritional Biochemicals Corporation, Cleveland, Ohio, and was freshly prepared.

Bacteria may have been transferred with the *Paramecium* from the stock culture; but the ambient medium as added daily for the test period was free from bacteria. In tests for a possible effect of kinetin on the bacterial population, Guttman and Back[7] found no change in its size or constitution. Lansford *et al.*[10] found no appreciable effect of kinetin alone on the growth of *Lactobacillus arabinosus*.

When Guttman and Back[6] re-analysed their results, recording division frequency for each day separately, their results showed a day-by-day pattern of divisions in kinetin-treated *Paramecia* which was approximately the same as the pattern for the controls, but at a higher level. Re-analysis of our Table 1 by this method, recording division frequency for each day separately, showed that the up-and-down pattern of the mean numbers of divisions for kinetin-treated *Paramecia* is the reverse of that for the control *Paramecia* in every case excepting for the third day in *Paramecia* treated with 0·5 and 1·0 p.p.m. kinetin. These show a decrease from day 2 to day 3, similar to the decreasing pattern for the controls. The re-analysis of the data on *Paramecia* treated with kinetin + IAA is shown in Fig. 1. The division pattern of the treated *Paramecia* is the reverse of the pattern for controls. Although the addition of IAA to the kinetin medium apparently reversed the inhibitory action of kinetin alone when the overall means for the three days are considered, day-by-day analysis shows that the reversal did not occur until day 2.

Woodruff[11], in numerous studies of division in *Paramecia*, found a regular cyclic rhythm of increase and decrease under normal conditions. The controls in our experiments and in those of Guttman and Back show day-to-day differences which might be part of such a cyclic rhythm, or which might be due to change in rate on transfer to a new medium.

In our experiments, the up-and-down rhythm pattern of division of *Paramecia* treated with kinetin was the reverse of the pattern for controls, that is, the number of divisions increased in treated *Paramecia* when it decreased in the controls, and vice versa. This also does not agree with the results of Guttman and Back, who found that the pattern of division for kinetin-treated *Paramecia* was similar to the pattern for the controls, with parallel increase and decrease in the number of divisions in all cases.

Guttman[12] in 1956 reported a stimulatory effect of kinetin on mitosis in cells of intact onion roots. Her data were obtained by counting mitotic figures in random fields of squash preparations. In similar work in which mitoses were counted in serial longitudinal sections of onion root tips, McManus[13] found an

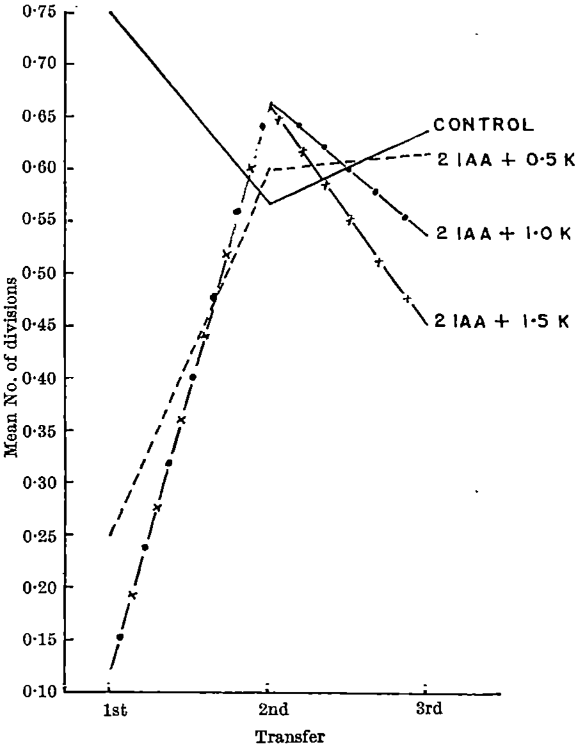

Fig. 1. Cell division in *Paramecium caudatum* treated with indole-3-acetic acid plus kinetin (parts per million). The influence of treatment on division frequencies after each of three daily transfers to new medium

inhibitory effect of kinetin, at comparable concentrations. Inhibition was also indicated by data obtained by Jensen and Pollock[14] in quantitative work on the deoxyribonucleic acid content of onion root tips treated with kinetin.

Whether or not kinetin occurs naturally in plant and animal tissue, clarification of the true nature of its effect on cell division under various conditions is of importance to our understanding of the growth process. Undoubtedly, interactions between kinetin and IAA and between them and other substances and events within the cell, which compel its division, must be very complex.

Cycle and Rhythm in the Ovulation of the Spider *Latrodectus geometricus* C. Koch

We define 'cycle' as that phenomenon represented by regular variations of internal origin. By 'rhythm', we understand a phenomenon represented by regular variations imposed by external conditions. 'Regularity' signifies a constancy of the interval separating two identical stages of the variation[1]. The ovulation of the cosmotropical spider *Latrodectus geometricus* C. Koch is at one time both cyclic and rhythmic.

Under laboratory conditions, with regular nutrition and prior fecundation, the adult *Latrodectus* lays an average of 22·56 cocoons at an interval of one every four days during the first part of its life. This interval becomes progressively longer until death intervenes. This metabolic ovarian cycle, established by observation of the laying of some thousands of cocoons, is illustrated in Fig. 1, which represents the percentage frequency (ordinate) of different time-intervals in days separating the laying of successive cocoons (abscissa)[2].

86·8 per cent of the cocoons are laid between 0230 and 0320 hr., with the relative maximum falling at 5.30. Under natural conditions this maximum is more sharply accentuated. Fig. 2 represents the observations made on several hundred cases, in which the numbers of cocoons produced (ordinate) are grouped against intervals of 1 hr. (abscissa).

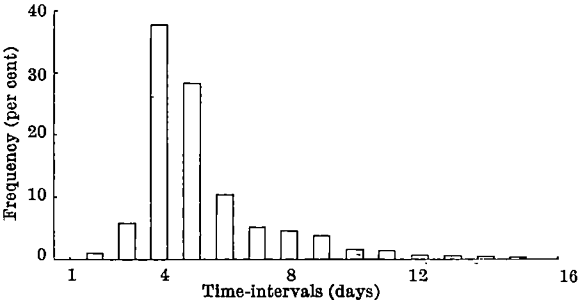

Fig. 1

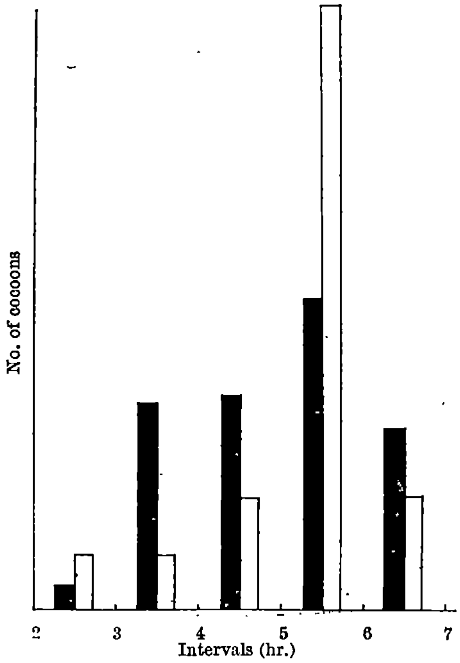

Fig. 2. ■, Laboratory; □, Nature

Observations on the production of 2,430 cocoons under varying controlled conditions (alternation of day and night with a displacement of 12-hr., period of daily illumination, temperature, humidity, time of feeding) have shown the only factor capable of influencing this rhythm, superimposed on the ovulation cycle, to be nycthemeral. By alternating the day and night cycle, the maximum intensity of ovulation can be shifted to fall between 1700 and 1800 hr., that is to say before an instantaneous change from obscurity to light, but the laying period is, however, more spread out than under normal conditions, 66 per cent of the cocoons being laid between 1400 and 2200 hr.[3]

Significance of the Regeneration of Lateral Plates of the Stickleback (*Gasterosteus aculeatus* L.)

The taxonomy of the stickleback (*Gasterosteus aculeatus* L.) has excited the interest of zoologists for more than two centuries. Even now there are many unexplained questions concerning the differentiation within the species. The most difficult to explain is the variable number of lateral plates covering the body of this fish.

My earlier investigation, already described[1], of the process of regeneration of the lateral plates seems to question the popular conception that small losses in plates are caused by the mechanical tearing off of the plates in natural conditions. When the lateral plates of the stickleback were removed with the cutis, then the connective tissue, the subcutaneous tissue and a thin layer of muscles were regenerated by the organism by differentiation of the mesenchyme tissue. Plates removed from a considerable area of the body regenerated at the same time. This excludes the possibility of their being regenerated only in the proximity of the untouched plates. The discovery of the regeneration of the lateral plates which had been cut away completely is interesting, because so far all experiments carried out with dermal bones (which have the same structure and origin as lateral plates) have shown that regeneration takes place only when they were cut away only partially[2-5].

Continuing the investigation has shown recently that the regeneration of the amputated parts of the body of the stickleback sets in relatively quickly. The epidermis fills up the losses of the parts of the body removed within six days. In about fifteen days connective tissue penetrates in between the epidermis and the regenerating muscles. After 30 days the connective tissue differentiates into loose, elastic and subcutaneous kinds of tissue. A germ of a lateral plate appears on about the fiftieth day of the regenerating processes. Between the 100th and 150th day of regeneration, the lateral plate is usually restored, but sometimes its shape is irregular. In the case of a partial amputation of lateral plates, restoration of the loss takes place more quickly; this is natural, because the regenerated part profits by the cells of the old tissue.

It seems that this investigation throws some light on the complicated problem of the individual mutability of stickleback which is conditioned, among other factors, by a variable number of lateral plates.

Spiracle Control in Dragonflies

Hoyle[1] has shown that carbon dioxide has a direct action on the neuro-muscular junction of the closer muscle of the second spiracle of the locust, reducing the electrical responses and the tension developed in spite of maintained stimulation of the motor axons in the transverse nerve. However, this peripheral control mechanism does not seem to play an important part in the regulation of the intact spiracle which, except during flight, remains firmly synchronized with ventilation[2]. It might be expected to play a more important part in an insect the spiracles of which are not always synchronized with ventilation, such as the dragonfly. The adults of four species of Aeschnid dragonflies, occurring in Great Britain, have been examined and none shows ventilation synchronization in spiracles 1, 2 or 3. In the 15 species of Libellulidae from Great Britain and Uganda which have been examined, however, spiracle 1 opens with abdominal inspiration and closes completely or partially with expiration: at rest, spiracles 2 and 3 remain closed, but they may join spiracle 1 as inspiratory spiracles for a brief period after struggling or flight.

Spiracles 1, 2 and 3 are similar to the abdominal spiracles in possessing a closer muscle and in being opened by a cuticular elastic mechanism. The activity of the closer is controlled by the interaction of two mechanisms. In the first a central reflex, initiated by any movement—usually flight—inhibits the streams of motor impulses in the median nerves to spiracles 1, 2 and 3 so that they open instantaneously. They remain open throughout flight. The second mechanism depends on the peripheral action of carbon dioxide, and the site of action is most probably the neuro-muscular junction of the closer as in the locust[1]. Oscilloscope records show that the pattern of motor impulses in the transverse nerve to the closer muscle remains unaltered while the spiracle opens to locally administered 5 per cent carbon dioxide. In Aeschnids the spiracle opens with irregular fluttering movements, but in Libellulids it starts immediately to make movements synchronized with ventilation, although the other member of the pair remains closed. Each spiracle of the pair receives identical motor input, since the axons in the median nerve divide into right and left transverse nerves. In Libellulidae the motor input nearly always shows a rhythm, increasing in frequency with expiration and decreasing with inspiration. The rhythm is very marked when ventilation is strong, but may disappear during weak ventilation. In the absence of carbon dioxide, the lower (inspiratory) frequency is adequate to maintain a tetanus in the closer and the spiracle stays shut. Local administration of 5 per cent carbon dioxide to the spiracle makes the lower frequency ineffective so that the spiracle opens during inspiration and recloses with expiration. In 5–10 per cent carbon dioxide the higher frequency also becomes partially or completely ineffective so that the spiracle remains open. Carbon dioxide in the thoracic ganglia stimulates abdominal ventilation and this in turn gives a more strongly marked rhythm in the thoracic transverse nerves. It has been shown that, unlike the locust, there is no rhythmic ventilation centre in the thorax and, after removal of the abdomen, treatment of the thoracic ganglia with carbon dioxide does not alter the patterns of motor impulses in the transverse nerves. The reaction can take place only via the abdomen.

In this way the insect possesses a facultative synchronization mechanism which allows the spiracles to be coupled to the ventilatory rhythm in the presence of low concentrations of carbon dioxide, and it is clear that the peripheral control mechanism plays an important part. Reduced oxygen tensions have no comparable affect. Possibly similar facultative spiracle synchronization has been observed in the cockroach[3], and such mechanisms in which variation takes place peripherally, while the contribution from the central nervous system remains largely unaltered, may reflect the need for the arthropod nervous system to economize in central connexions[4].

The sensitivity of the response of the spiracle muscle to carbon dioxide has been shown to depend on the state of hydration of the insect. In partially desiccated dragonflies the spiracles do not open in less than about 5 per cent carbon dioxide in air, and after flight they close immediately. In well-hydrated insects they open in 1–2 per cent carbon dioxide, and they may remain open for as long as 2 min. after flight. Experimentally produced variations in the osmotic pressure of the hæmolymph have been shown to alter the spiracle muscle's sensitivity directly, both before and after denervation, so that internal osmometers relaying to the central nervous system need not be postulated, and again the reaction takes place entirely peripherally.

MICROBIOLOGY

Occurrence of *Salmonellae* in Domestic Animals and Poultry in India

THIS communication presents the results of an investigation into the occurrence of *Salmonellae*, usually in the symptomless carrier-state, in domestic animals and poultry in the State of Uttar Pradesh in India.

Bacteriological examination was mainly confined to fæcal samples; however, small pieces of liver, spleen, gall-bladder, lungs and intestine with its contents were also collected from domestic animals and poultry for examination.

The methods of isolation of *Salmonellae* used were on the lines adopted by Smith and Buxton[1] and Edwards *et al.*[2] with minor modifications. *Salmonella* genus-specific 0–1 bacteriophage was also used as advocated by Cherry *et al.*[3]. The serological typing was done by one of us at the Armed Forces Medical College, Poona. The strains were also sent to Dr. P. R. Edwards, Chamblee Georgia, U.S.A., and to Dr. Joan Taylor, Salmonella Reference Laboratory, London, for serological typing.

A total number of 2,970 domestic animals including poultry (1,332 fowls; 206 dead in shell embryos; 68 pigeons; 110 ducks; 455 cattle; 290 buffaloes; 163 sheep; 91 goats; 247 pigs and 18 rats) were examined during the course of the investigation. The occurrence of *Salmonella* species was demonstrated in 24 fowls, 7 dead in shell embryos, 1 duck, 8 cattle, 9 buffaloes, 4 goats, 3 pigs and 1 rat, making a total of 57 isolations.

Seventeen species of *Salmonellae*, including a new sero-type encountered during this investigation, are as follows (the figures in brackets indicate the number of isolations):

Fowls: *anatum* (2); *champaign* (2); *chester* (1); *hvittingfoss* (2), *matopeni* (1); *pomona* (1); *richmond* (3); *san-diego* (1); *stanley* (1); *weltevreden* (10).
Dead in shell-embryos: *richmond* (7).
Duck: *san-diego* (1).
Cattle: *aba* (1); *charity* (1); *magwa* (2); *matopeni* (1); *pomona* (2); *mathura* (1).
Buffaloes: *anatum* (1); *enteritidis* var. *jena* (1); *magwa* (1); *pomona* (1); *typhimurium* (1); *weltevreden* (4).
Goats: *magwa* (1); *matopeni* (1); *weltevreden* (2).
Pigs: *anatum* (1); *newport* (1); *Stanley* (1).
Rats: *anatum* (1).

A new species of *Salmonella*, which has been named *Salmonella mathura* with antigenic formula (9), 46 : i : e, n, z 15, has been isolated from cattle. The biochemical behaviour of this species, as studied by Dr. F. Kauffmann, International Salmonella and Escherichia Centre, Copenhagen, is as follows: adonitol, rhamnose, salicin, inositol, lactose and sucrose: negative after 30 days.

Positive reaction after 1 day in: dulcitol, sorbitol, arabinose, xylose, maltose, mannitol, glucose and trehalose. Gas production in mannitol and glucose. Stern's glycerolfuchsin broth negative after 8 days.

Hydrogen sulphide in ferrous chloride gelatin, negative. Gelatin, negative.

Ammonium glucose and ammonium citrate, positive. Potassium nitrate, positive; Voges-Proskauer, negative; methyl-red, positive; urea, negative.

d-tartrate, +1; *l*-tartrate, delayed and irregular, *i*-tartrate, +2; sodium citrate, +2; mucate, +1.

It is interesting to note that several of the species which probably have been isolated so far only from human beings are being encountered in animals. The importance of such occurrence from the epidemiological and public health point of view is obvious and further work is in progress. Investigation is also being conducted for the further characterization of the new species, *S. mathura*.

We are indebted to Major L. D. Sachdeva, of the Armed Forces Medical College, Poona, for the help and guidance in sero-typing the cultures, and Dr. Joan Taylor, of the Salmonella Reference Laboratory, Colindale, London, and Dr. P. R. Edwards, Chamblee Georgia, U.S.A., for sero-typing of the strains. We gratefully acknowledge the kind help of Dr. William B. Cherry, Chamblee Georgia, U.S.A., for

supplying 0–1 phage, and of Dr. J. B. Shrivastava, National Salmonella Centre, Kasauli, Punjab, for his help, and Dr. F. Kauffmann, International Salmonella and Escherichia Centre, Copenhagen, for final confirmation of the new species, and to Sri C. V. G. Choudary, principal of the Veterinary College, Mathura, for providing the necessary facilities.

Transfer of Virulence in *Rhizobium trifolii*

So far, very few reports concerning transformations in *Rhizobium* have appeared. Krasilnikov[1] reported as early as 1941 that non-infective strains turned infective when they were grown for several months in a filtrate of a highly infective strain. By ultrasonic treatment and with preparations of deoxyribonucleic acid (DNA) Balassa[2,3] has obtained transformations concerning several properties, for example, infective ability under formation of new host specificity, increase or decrease in nitrogen-fixing ability, variation in colony types, and changes in antigenic structure.

I happened to meet with a case of transformation in *Rhizobium trifolii*. As part of a study of the infection process a polysaccharide was prepared from an infective strain[4]. As it had been observed (unpublished results) that inoculated plants formed nodules 1–2 days earlier when this preparation was added, the polysaccharide was added to plants inoculated with a non-infective strain to see whether it might help the avirulent bacteria to overcome the infection barrier.

The clover strain *A* used in the experiment described here has been studied thoroughly by Nutman[5,6]. The original strain lost its infection ability in 1940 (called Bart *A*), but a virulent line (*A* 1) was contained in an isolate from a nodule produced by the original strain. *A* 11 is an avirulent and *A* 121111 a virulent line, isolated from *A* 1. 226, the other clover strain, is a Swedish strain isolated by Bjälfve and so far as known not related to the *A* strain.

A polysaccharide from strain 226 was prepared[7] from a 2-wk.-old culture (Dorn's A_5-medium[8]) by precipitating the whole culture in alcohol, dissolving the precipitate in water and separating the cells by centrifugation. The clear solution was deproteinized according to Sevag[9], precipitated again, and dialysed against distilled water. After another precipitation, the preparation was dried *in vacuo* and a white water-soluble material was obtained.

Seeds of *Trifolium repens* (var. Morsö, Svalöf, Sweden) were germinated aseptically in tubes containing slopes of Jensen's seedling agar. After 2 days, they were inoculated with a few drops of a suspension of *Rhizobium* (Table 1, series 1–8). Immediately after inoculation, 2 mgm. of the 226 polysaccharide in water solution was added. The appearance of the first nodule in days after inoculation and the number of nodules after 2, 3 and 4 wk. are recorded in Table 1.

Table 1. PLANTS OF *Trifolium repens* INOCULATED WITH AVIRULENT (BART *A* AND *A* 11) AND VIRULENT (*A* 121111 AND 226) CLOVER BACTERIA WITHOUT (–) AND WITH (+) POLYSACCHARIDE PREPARATION FROM STRAIN 226 (2 MGM./TUBE). EACH TUBE CONTAINED 10 ML. OF JENSEN'S AGAR. THE NUMBER OF NODULES ARE MEAN VALUES OF FIVE REPLICANTS

Series No.	Bacterial strain	Poly-saccharide addition	Appearance of the first nodule in days after inoculation	Mean number of nodules per tube after 2 wk.	3 wk.	4 wk.
1	Bart *A*	–	–	–	–	–
2	*A* 11	–	–	–	–	–
3	*A* 121111	–	10	3·3	8·5	12·5
4	226	–	9	2·7	7·0	10·0
5	Bart *A*	+	9	2·5	7·3	9·3
6	*A* 11	+	9	3·5	9·0	12·0
7	*A* 121111	+	7	6·7	12·0	15·0
8	226	+	7	5·8	8·5	10·3
9	Bart *A*	–	–	–		
10	Bart *A*·2	–	8	4·2		
11	Bart *A*	+	8	6·4		
12	Bart *A*·2	+	6	7·4		

Bacteria from the nodules produced by the formerly avirulent Bart *A* in the presence of the polysaccharide were isolated (Bart *A*·2). The colonies had the smooth appearance of 226, not rough like Bart *A*.

New seedlings were inoculated with Bart *A* and Bart *A*·2 with and without polysaccharide 226 (Table 1, series 9–12). From this experiment it is evident that Bart *A* has become infective. A serological test showed that Bart *A*·2 did not react with antiserum prepared from the *A* strain (*A* 121111), indicating that the new strain has not recovered the antigenic properties lost by the *A* strain, but has gained something new, most likely from strain 226. Investigations into the nutritional requirements of the involved strains showed that strain 226 and Bart *A*·2 are greatly stimulated by pantothenic acid, but that Bart *A* is not.

The most likely explanation of the above results is that a transformation induced by the polysaccharide preparation (which might contain DNA) has taken place. This evidence and the earlier report[4] point to the surface material of the *Rhizobium* cells as playing an important part in their ability to infect the root hairs of the appropriate host.

Detailed work on the importance of the capsular material for the infection process is in progress and will be published elsewhere.

I wish to express my indebtedness to Dr. P. S. Nutman for the opportunity to work at his laboratory. My stay at Rothamsted was financed by a grant from Magnus Bergvalls Stiftelse.

VIROLOGY

Infectious Ribonucleic Acids derived from Mouse Brains infected with Two Kinds of Arbor Virus Group *B*

INFECTIOUS ribonucleic acid (RNA) has been extracted by phenol treatment[1] from cells infected with animal viruses. In Group *B* of the arbor viruses, it has been recently reported that the RNA extracted from mouse brain infected with Murray Valley encephalitis virus[2] or Japanese *B* virus[3] and from Ehrlich ascites tumour cells infected with West Nile encephalitis[4] are infectious. The purpose of this present communication is to add a datum concerning the extraction of infectious RNA from mouse brains infected with dengue fever virus to the reports of viral RNA already published, and to compare the effects of cold- and hot-phenol extractions on the yields of infectious RNA from the cells infected with Japanese *B* encephalitis virus and dengue fever virus, respectively.

Five-day-old mouse brains infected intracerebrally with the Hawaiian strain of dengue fever virus (*M*-184) and three-week-old mouse brains infected with the Nakayama strain of Japanese *B* encephalitis virus (*M*-55) were employed as the sources of the materials for extraction of RNA. The brains were removed from exsanguinated mice shortly after the appearance of signs of involvement of the central nervous system, ground in a chilled mortar, and a 10 per cent suspension was made with sterile distilled water. Coarse particles were removed by low centrifugation, and the supernatant fluid was used for the experiment. The supernatant fluids were extracted three times with an equal volume of cold 80 per cent phenol at 4° C. for 3 min. following the procedure of Gierer and Schramm[1], or with an equal volume of molten phenol (50° C.) and shaken at 50° C. for 3 min. by Wecker's method[5]. After three such extractions the aqueous phase was shaken five times with peroxide-free ether and the excess ether was removed by bubbling with nitrogen. The aqueous phase obtained by each extraction was reconstituted to the original volume with sterile distilled water. Infectivity titres of the samples, expressed as LD_{50}, were determined by the intracerebral inoculation of serial 10-fold dilutions in mice, 0·02 ml. for three- to five-day-old mice and 0·03 ml. for three-week-old mice. Clarified 10 per cent infected brain suspension and the RNA preparation were regarded as 10^{-1} dilution. The results obtained are shown in Table 1.

Both infectious RNA of Japanese *B* encephalitis virus and dengue fever virus could be easily extracted by phenol treatment, and the yields of infectious RNA of these viruses were the same as that of poliovirus, that is, they amounted usually to about 0·1–0·01 per cent of the crude virus preparation. There were no differences between the effects of cold- and hot-phenol extraction on the yields of RNA derived from the two viruses.

The ultra-violet absorption spectra of these preparations of RNA were typical for nucleic acid. If such an extracted preparation was treated with 50 μgm./ml. of ribonuclease for 10 min. at room temperature prior to inoculation, its infectivity was completely abolished, whereas identical treatment of the virus suspension had no such effect. The preparations of RNA of these viruses had no hæmagglutinating activity under the conditions which were used for these viruses.

Table 1. INFECTIVITY OF TWO KINDS OF ARBOR VIRUS GROUP *B* AND RIBONUCLEIC ACID PREPARATIONS

Material	Animal for titration (−log LD_{50}/ml.)	
	Suckling mouse	Adult mouse
Japanese *B* encephalitis virus:		
Crude virus	8·9	8·5
RNA extracted by cold phenol	4·7	4·2
RNA extracted by hot phenol	5·5	3·8
Virus + RNase 50 μgm./ml., 22° C.; 10 min.	9·2	7·5
RNA* + RNase 50 μgm./ml., 22° C.; 10 min.	—†	—
Dengue fever virus:		
Crude virus	8·1	6·0
RNA extracted by cold phenol	4·7	4·5
RNA extracted by hot phenol	4·9	5·0
Virus + RNase 50 μgm./ml., 14° C.; 10 min.	8·0	*N.T.*
RNA* + RNase 50 μgm./ml., 14° C.,; 10 min.	—	*N.T.*

* RNA was extracted by hot-phenol treatment.
† No mice died when given undiluted inoculum.
N.T. = Not tested.

It might be noted, as indicated in Table 1, that, in the case of dengue fever virus, there were no differences between the infectivity titres of RNA for suckling mice and that for adult mice; whereas if adult mice were used for titration, the titres of the crude virus were approximately 100 times lower than that in suckling mice. Therefore, the ratio of virus to RNA in adult mice was much nearer unity than that in suckling mice.

Experiments are now being carried out in the extraction of RNA from adult mouse brains infected with dengue fever virus and suckling mouse brains infected with adult mouse-adapted dengue fever virus.

Relationship of Tobacco Mosaic Virus (TMV) Lesion Number and Concentration to the Rate of Lesion Production on Pinto Bean

IN experiments which required the daily counting of TMV lesions on pinto bean leaves (*Phaseolus vulgaris* L.) for the purpose of determining specific rates of lesion-appearance, it was noted that those leaves which had the greatest final number of lesions produced a greater percentage of their lesions earlier. Since comparisons of rates of lesion development could be seriously affected by differences arising from this, an attempt was made to determine its cause and extent.

Bald[1] had observed the same phenomenon when potato virus *X* was inoculated into *Nicotiana tabacum* L. (var. White Burley), but could not obtain these results when this virus or TMV was inoculated into *N. glutinosa* L. He suggested that either adjacent incipient lesions enhanced production of early lesions or else the greater the number of infective particles entering an infection site, the more rapid the rate of virus multiplication and hence lesion appearance. The first suggestion is not compatible with our results and the second seems unlikely, since it is generally held that only one virus particle can infect one site[2,3].

According to Lauffer and Price[3] the rate of development of symptoms should be a function of concentration of virus, since Bryan and Beard[4] had observed this to be true for rabbit papilloma virus. They postulated that high virus concentrations should be associated with a high probability that every susceptible spot in a scarified area would become infected. Our results with TMV tend to confirm this hypothesis.

In order to investigate this problem more thoroughly a series of concentrations of purified TMV in distilled water, 7, 129, 430, 1,290 and 12,900 μgm./ml., was inoculated to primary pinto bean leaves selected randomly from 10-day-old plants. Inoculation was accomplished by rubbing several drops of virus solution gently with a glass rod over the 600 grit 'Carborundum' sprinkled leaf surface. 1 hr. after inoculation, leaves were washed in running tap water and incubated in a constant light and temperature chamber at 30° C. Lesions were counted at intervals, until new lesions failed to appear. The percentage of the final total of new lesions appearing at each count was plotted against time after inoculation (Fig. 1).

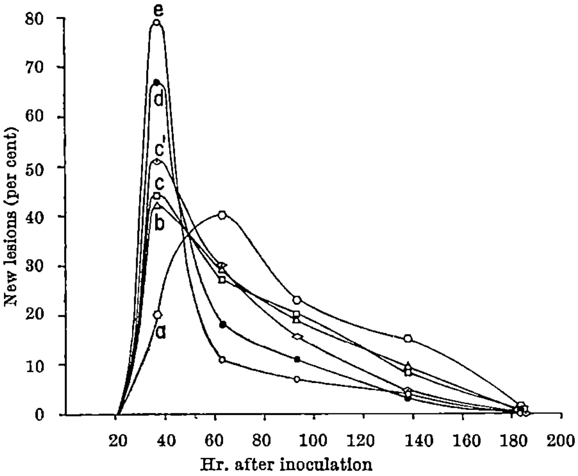

Fig. 1. The effect of tobacco mosaic virus concentration on the rate of appearance of lesions on primary leaves of pinto bean. Virus concentration, number of half-leaves and mean number of lesions per half-leaf for each curve: (*a*) 7 μgm./ml., 6, 9; (*b*) 129 μgm./ml., 8, 48; (*c*) 430 μgm./ml., 8, 61; (*c'*) 430 μgm./ml., 4 of the 8 half-leaves of (*c*) with the greatest number of lesions, 82; (*d*) 1,290 μgm./ml., 6, 60; (*e*) 12,900 μgm./ml., 6, 78. Note that for each time the number of new lesions appearing in the graph is expressed as the percentage of the final total

Examination of the count 37 hr. after inoculation (Fig. 1) shows conclusively that the percentage of new lesions is a function of the virus concentration. It is clear that higher concentrations bring about a higher percentage of lesions appearing early and a lower percentage of those appearing late than do lower virus concentrations. It appears, too, that the difference in the initial rate of appearance of lesions becomes less pronounced as the concentration increases.

Acceleration in appearance of lesions by higher concentrations of TMV was also obtained in two other experiments; one, comparing 0·5 μgm./ml. with 50 μgm./ml. TMV on 18 pinto bean leaves where the average number of lesions per half-leaf for the low concentration was 10 and for the high concentration 62, and the other comparing TMV at 5 μgm./ml. with 50 μgm./ml. on 6 pinto bean leaves where the mean number of lesions per half-leaf for the low concentration was 38 and for the high concentration 93.

An additional observation is that, even though the average number of lesions per half-leaf produced by the 430 μgm./ml. and 1,290 μgm./ml. inocula is about the same, a much greater percentage of the lesions appeared earlier in the case of the more highly concentrated inoculum, as can be seen by comparing the 37 hr. counts (Fig. 1, *d*, *c*). On the other hand, *c'* in Fig. 1, which represents the four half-leaves of the 430 μgm./ml. inoculated group with the most lesions, shows an increased rate of development of lesions as compared with this group as a whole (Fig. 1, *c*, *c'*). Additional comparisons of leaves with high and low lesions counts in four separate experiments averaging fourteen leaves each have confirmed this finding. From calculations[3] based on the number of mixed infections obtained from TMV and aucuba mosaic virus on *N. langsdorffii* Weinm., it seems reasonable to assume that a number of sites within the many-celled area that comprises a lesion by the time it is seen are often exposed and infected in the process of mechanical inoculation. It would follow also that the probability of virus particles initiating an infection at these sites increases with the concentration of the inoculum. Such composite lesions would be likely to appear sooner. The virus concentration is, however, only one variable.

Noting the range of time over which new lesions form for the relatively dilute 7 μgm./ml. inoculum (Fig. 1, *a*), where the percentage of composite lesions should be at a minimum, it appears that sites must vary considerably in the time required for them to produce virus and finally a visible lesion. If such a variability in sites exists, it is possible that at higher concentrations, when more than one site within a lesion area is infected, the site which produces virus most rapidly will determine the time of appearance of the lesion. The time of appearance, then, would depend on the probability of an early site being infected and would be a function of the total number of interactions of virus sites. It is clear that this latter condition depends not only on virus concentration but also on variability in host susceptibility and inoculation technique as well.

This leads us to our finding that when a variety of lesion counts is obtained from a given inoculum, the leaves having the greatest final number of lesions have also the highest percentage of early appearing lesions. Here again, differences in inoculation and host susceptibility have increased the number of interactions of virus sites, resulting in both a higher number of lesions and a higher number of susceptible sites occupied within a lesion area. This results in more and earlier lesions.

It seems apparent, then, that the number of lesions is not what determines the rate of appearance of lesions, but is only a reflexion of the infectivity of the inoculum, inoculating technique and host susceptibility, all of which actually affect the rate. Number of lesions can, however, be used as an index of the number of virus-site interactions.

This work was aided by an American Cancer Society Institutional grant.

Chromatography of Tobacco Mosaic Virus (TMV) on Chitin Columns

While performing experiments on infected tobacco plant fibre to determine the virus-releasing enzymic activity of crude mushroom extracts (Townsley, P. M., unpublished results), it was noted that added chitin strongly adsorbed tobacco mosaic virus. At least a portion of the adsorbed virus could be released with concentrated phosphate buffers. This investigation describes the chromatographic properties of chitin for TMV.

90 gm. of chitin (Eastman Organic Chemicals) was reduced to a fine powder in a porcelain–'Carborundum' ball mill, in about 18 hr. The powder was suspended in 1 litre of *N* sodium hydroxide, stirred for about 0·5 hr. and collected in a Buchner funnel. The chitin pad was washed thoroughly with distilled water and then resuspended in 1 litre of 2 *N* hydrochloric acid. After settling for at least 0·5 hr. the top milky layer was decanted and discarded. The sediment was collected on a Buchner funnel, washed first with water, then with 95 per cent alcohol, and finally with ether.

10 gm. of prepared chitin was suspended in 250 ml. of water, and allowed to settle for 20 min. The top layer was discarded. The sediment slurry, now containing approximately 5 gm. of air-dried chitin, was poured into a chromatographic column, to form a column 17 × 1·3 cm. The column was washed with 25 ml. of 1 *N* hydrochloric acid, followed by 50 ml. of water, then 150 ml. of 0·1 *M tris*–hydrochloric acid, *p*H 6·8, and finally equilibrated with approximately 75 ml. of 0·01 *M tris*–hydrochloric acid, *p*H 6·8 (similar equilibration of the column with phosphate buffer, *p*H 6·8, prevented the column from adsorbing all the added TMV). The eluate from the column was approximately *p*H 6·8.

0·5 ml. of tobacco mosaic virus solution containing 0·3–2 mgm. of virus in 0·01 *M* sodium phosphate buffer, *p*H 6·8, prepared by two alternate cycles at 6,000*g* and 78,000*g* (ref. 1), was added to the column and the virus washed into the column with three successive 1-ml. aliquots of 0·01 *M tris*–hydrochloric acid, *p*H 6·8. 3 ml. of the latter buffer was then placed on the column and the column connected for linear gradient elution. The linear gradient progressed from water to 0·5 *M* K_2HPO_4. The eluate was collected in 4·3-ml. aliquots at 10-min. intervals in a fraction collector equipped for continuous optical density recording at 254 mμ.

As measured by optical density the virus was almost wholly accounted for in the two eluted peaks (Fig. 1). The results were reproducible, but the amount of virus in each peak varied. No explanation is offered for the appearance of two major peaks rather than one as might have been expected from the virus purified by ultra-centrifugation.

Material from both the peaks was birefringent and infective. Preliminary, comparative infectivity tests directly on elution, using six half-leaves of the local lesion host, *Nicotiana glutinosa* L., for each of the peaks, indicated that the material eluted at *p*H 7·2 was from four to ten times as infective as that eluted at *p*H 7·7. Spectrophotometric measurements gave a 260/280 mμ ratio of 1·23 and 1·29 respectively, for the peaks in the eluting solvent.

As a chromatographic agent for TMV chitin would appear to be very useful in view of the mild treatment required for adsorption and elution of the virus.

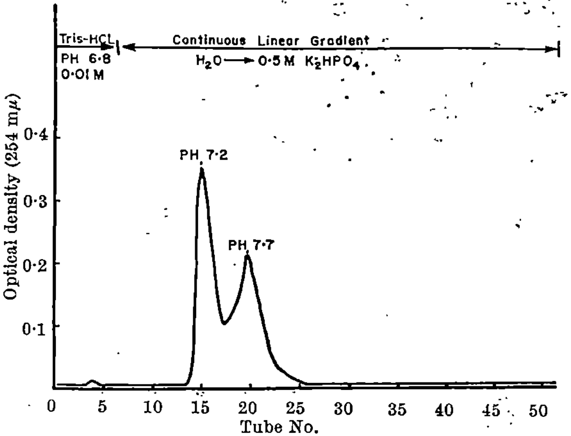

Fig. 1. An elution curve of tobacco mosaic virus from a chitin chromatographic column

Preliminary experiments have also shown that chitin may be used with similar ease for nucleic acid chromatography.

CYTOLOGY

Peripheral Position of Sex Chromatin

In examining buccal smears for sex chromatin, one finds a surprisingly high incidence of sex chromatin bodies not merely at the nuclear membrane but also more precisely at the periphery of what appears to be a disk-shaped nucleus. The following discussion will provide evidence that, as in tissue cultures[1], the sex chromatin is characteristically at the edge of the nuclear disk in squamous cells *in vivo*. In establishing this let us first consider that squamous nuclei *in vivo* are flattened. This may be seen in mucosal smears when a mucosal fragment is folded over (Fig. 1). It is evident, too, that the cells in fragments in the smear maintain the same relative position to one another that they had *in vivo*, and that one is seeing the cells as one would have seen them in looking directly down on to the mucosal surface. Further, in most nuclei which can be reliably scored,

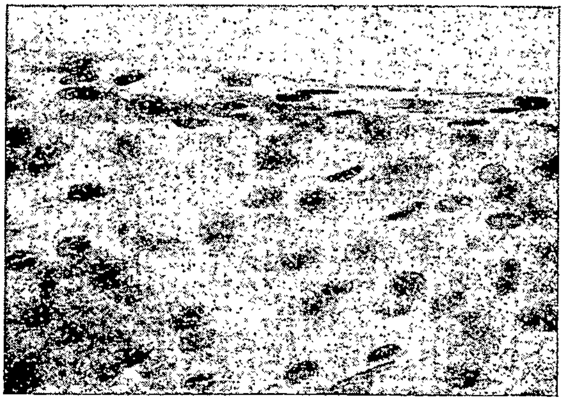

Fig. 1

one can visualize all, or almost all, the nucleoplasm by focusing up and down. Thus one can visualize the sex chromatin regardless of its position in the nucleus.

What is the probability that the sex chromatin body would, by chance alone, appear at the periphery of nuclei as they lie in the optical plane ? Let us assume that the nucleus as observed is an approximate ellipse. If the sex chromatin body lies within a zone bounded by the edge of the nucleus and a locus of points no greater than the thickness of the sex chromocentre measured from the outer to the inner edge (that is, this distance is the altitude when the sex chromatin body is triangular, the radius if the chromatin is plano-convex, and so on), then it will appear to be at the edge of the nucleus. The probability that the sex chromatin will be at the periphery is found by dividing the area of the peripheral zone by the total area of the nuclear ellipse. (Calculations based on volumes are more complicated but give results of the same order of magnitude.)

Ten positive nuclei were selected at random, photographed, and the appropriate dimensions determined. The average thickness of the sex chromatin was slightly less than $0{\cdot}6\mu$, while the nuclei averaged about $7{\cdot}2 \times 9{\cdot}4\mu$. $0{\cdot}6\mu$ is smaller than the average figure reported by Prince, Graham and Barr[2] for the short axis of the sex chromatin body, hence in order to weigh the assumptions against the inference being favoured here, the larger figure will be used. The small area in question, that is, the numerator of the probability fraction, is found to a satisfactory approximation by multiplying 0·8 by the circumference of the ellipse. If the width of nucleus is $2a$, the length is $2b$, then the numerator is $0{\cdot}8 \times 2\pi\sqrt{\{(a^2 + b^2)/2\}} = 21\mu^2$; the denominator equals the area of the nuclear ellipse, $\pi ab = 54\mu^2$. Hence the probability that the sex chromatin will lie at the periphery of the nuclear disk equals 21/54 or, approximately, $P = 0{\cdot}39$; that is, about 39 per cent of the positive nuclei might be expected to show sex chromatin at the periphery by chance alone.

Good thionin-stained[3] buccal smears from ten subjects were used in determining the actual incidence of peripheral sex chromatin. One hundred nuclei were counted as being negative, unscorable, or as having peripheral or non-peripheral sex chromatin bodies. Nuclei were listed as unscorable if the observer could not decide whether they were positive or negative because the nuclei were pyknotic, folded over, disrupted or the like. They were scored as having non-peripheral sex chromatin if they had a non-peripheral chromocentre comparable in size (but not necessarily in morphology) to the sex chromatin. Counts were made by me (observer A), and by another microscopist (observer B). The latter had no knowledge of the purpose of the counts. On the average for both observers, about 86 per cent of the positive nuclei showed the sex chromatin at the periphery. Generally higher counts of observer A could properly be attributed to greater experience with sex chromatin assay, but unconscious bias cannot be ruled out.

Since observer B found a somewhat smaller percentage of peripheral chromocentres than did observer A, observer B's data are used in a test of significance. Observer B counted 252 positive nuclei of which 206 had peripheral chromatin bodies, while in 46 there were non-peripheral bodies. Using the theoretical expectation of 39 per cent peripheral chromocentres gives corresponding figures of 98 peripheral and 154 non-peripheral. $\chi^2 = 199{\cdot}5$, $P < 0{\cdot}005$. This evidence favours the view that the sex chromatin is characteristically at the periphery of the nuclear disk in smears, and since the relative orientation and shape of the nuclei are similar, the same observation applies to cells *in vivo*.

In addition to conditions in tissue cultures[1] mentioned here, preferential localization of sex chromatin has been described also for the cigar-shaped nuclei of smooth muscle cells[4], where the chromatin tended to be at one tip or the other. The mechanisms responsible for these localizations remain to be elucidated.

This work was supported in part by a U.S. Public Health Service research grant C–4866 (C1) Genetics, National Cancer Institute.

I thank Dr. Robert Day and his staff at the Sonoma State Hospital, California, for providing the buccal smears; and Mr. Steven Storey, Stanford University School of Medicine, who acted as observer B.

Chromosomal Elimination induced by 6-Aza-Uracil

DURING preliminary work in this Laboratory dealing with the effects of some antimetabolites on cell division in *Allium cepa*, it was noted that 6-aza-uracil brings about chromosomal elimination. This elimination occurred at metaphase and anaphase. Root tips from bulbs after reaching a length of 2–3 cm. were treated for 6 hr. with a 1 per cent aqueous solution. The solution was prepared by first grinding the powder and dissolving it in warm tap water. In order to clarify the location of the spindle attachment region of the chromosomes the root tips were treated with a 1 per cent aqueous solution of colchicine for a half-hour prior to fixation. On each preparation the number of normal metaphases, anaphases and telophases and the number of these stages showing elimination were counted. The eliminated chromosomes were studied in detail to determine whether or not the same chromosomes were always eliminated. Aceto-orcein smears and sections stained in iron alum hæmatoxylin were used.

Following 6-hr. treatment with the chemical 13 per cent of the division figures showed eliminated chromosomes. Further examination of mitotic figures indicated that anaphase figures showed this phenomenon more frequently than any other stage with an average of 31·7 per cent of the figures showing elimination. In different roots anaphase elimination ranged from 16 to 54 per cent.

Of 456 metaphases analysed, 6·4 per cent showed eliminated chromosomes. Of these, 66 per cent eliminated one chromosome (Fig. 1A), 24 per cent eliminated two chromosomes, 7 per cent eliminated three chromosomes and 3 per cent eliminated six chromosomes. In most of these cells the metaphase chromosomes were clumped and the eliminated

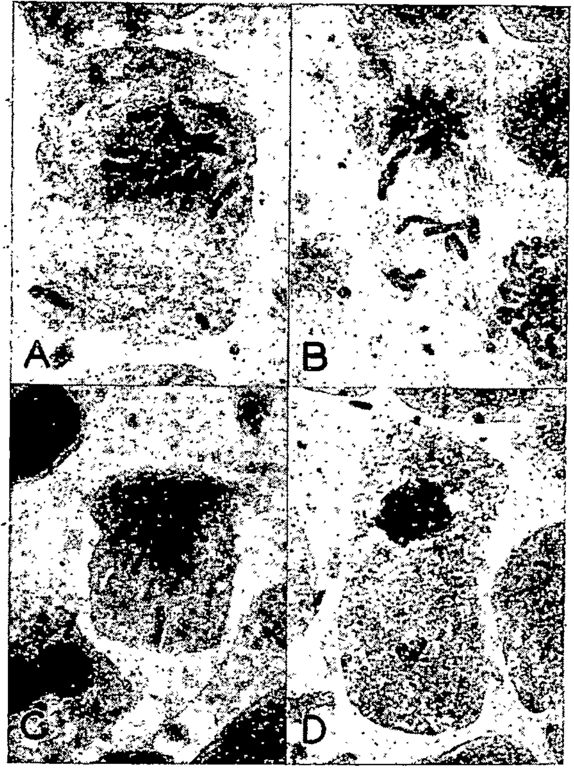

Fig. 1. Photomicrographs of aceto-orcein smear preparations of cells from the root tip of *Allium cepa* showing chromosomal elimination. *A*, metaphase; *B*, anaphase; *C*, anaphase; *D*, telophase. (× 750)

chromosomes were some distance from this mass and near the cell membrane. Sectioned material showed that these divisions with eliminated chromosomes occur in both the plerome and the periblem of the meristematic region. The eliminated chromosome was not always the same. Chromosomes with median, sub-median and sub-terminal centromeres were eliminated. These nuclei were apparently in prometaphase when affected by the chemical.

The anaphase picture is even more aberrant. In some cases two anaphase groups were noted with lagging chromosomes. It is assumed that such cells were in anaphase when influenced by the chemical. In other cases one large anaphase group was present with a number of chromosomes scattered throughout the cell (Fig. 1*B*). A similar effect was noted by Deysson[1] in *Allium sativum* following treatment with sodium oxalate and sodium citrate. In still other cases one large anaphase group was present with a single eliminated chromosome near the periphery of the cell (Fig. 1*C*). In other cases there appears to be no orientation at all. Two hundred and fifty-two anaphase figures were analysed. Of these 31·7 per cent showed eliminated chromosomes. Of these cells showing elimination 35 per cent eliminated one chromosome, 15 per cent eliminated two chromosomes, 16·3 per cent eliminated three chromosomes, 10 per cent eliminated four chromosomes, 7·5 per cent eliminated five or six chromosomes, 3·7 per cent eliminated eight chromosomes and 2·5 per cent eliminated nine or ten chromosomes. The types of chromosomes were eliminated at random.

At telophase in most cases there was a tightly clumped mass of chromosomes in various stages of reversion with one, two, three or four chromosomes near the periphery of the cell forming micronuclei (Fig. 1*D*). In other cells there were two telophase groups of chromosomes, but with apparently varying chromosome numbers. Even following normal anaphases cell-plate formation is apparently interfered with and binucleate cells frequently result. It is possible that these cells were affected in late anaphase, since anaphase separation itself was not interfered with. In those cells showing chromosomal elimination, the resulting nuclei are frequently of unequal size. Telophase figures were difficult to analyse. Of 210 cells studied, 11 cells or 5·2 per cent showed eliminated chromosomes. Of the cells 54·5 per cent eliminated one chromosome and 18·2 per cent eliminated two chromosomes.

Several investigations have been undertaken to ascertain the exact mechanism responsible for chromosomal elimination. Geyer-Duszynska[2] proposed that certain cytoplasmic factors inhibit chromosomal elimination, but she did not suggest any mechanism for the initiation of elimination of chromosomes. However, Avanzi[3] threw some light on the subject by showing that thallium acetate inhibits the functioning of the centromere in some chromosomes which afterwards lag at anaphase. Brachet[4] and Janaki-Ammal[5] also suggested a defective centromere as an explanation for chromosomal elimination. Nicklas[6,7] stated that elimination of chromosomes was due to failure of normal chromosomal fibre action. Vaarama[8] presented evidence that split spindles and timing disturbances resulted in the uneven distribution of chromosomes at the end of metaphase and his diagrams show the failure of some chromosomes to be included in the spindle structure.

Elimination of chromosomes by treatment with 6-aza-uracil may find a possible explanation in the fact that this substance is an analogue of uracil which is a normal constituent of ribonucleic acid. Davies[9] showed that in situations where the normal nucleic acid metabolism of the cell has been upset, the centromeres behave abnormally. He stated that a close interrelationship exists between the centromeric activity, nucleic acid metabolism and chromosomal behaviour. Evidence that ribonucleic acid is needed for the functioning of the spindle was reported by Kaufmann and Das[10], who showed that after treatment with ribonuclease, mitotic abnormalities were found, such as contraction, stickiness, adhesion and clumping of chromosomes, production of aneuploid and polyploid chromosome complexes, tripolar and multipolar spindles, binucleate cells and lagging of chromosomes at anaphase.

This investigation was aided by a grant (*G* 7091) from the National Science Foundation.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Tutorial Student (graduate or about to graduate) in Geography to read for a higher degree and give a limited amount of assistance by demonstrating—The Registrar, King's College (University of London), Strand, London, W.C.2 (August 9).

Lecturer (with a good honours degree, and teaching and/or research experience) to teach Physics to General Degree and G.C.E. Advanced Level; and Grade B Assistants (2) (preferably with teaching and/or research experience) to teach (*a*) Physics and (*b*) Mathematics—The Principal, Norwood Technical College, Knight's Hill, London, S.E.27, quoting Ref. FE.3a/N/1926/7 (August 12).

Research Assistant (with a first- or second-class honours degree in physics, and prepared to register for a higher degree) in the Department of Physics for work in the field of electron spin resonance—The Registrar, The University, Nottingham (August 12).

Lecturer or Assistant Lecturer (with a good honours degree in electrical engineering or physics, with special qualifications in one of the following branches: electrical machines, plasmas, materials, high vacuum or solid state electronics) in the Department of Electrical Engineering—The Secretary, The University, Edinburgh (August 14).

Lecturer (with a specialist interest in and experience of climatology and meteorology) in Geography—The Registrar, University College, Singleton Park, Swansea (August 14).

Assistant (with a special interest in pig husbandry) in Animal Husbandry—The Secretary, The University, Aberdeen (August 19).

Demonstrators in the Department of Geology—The Registrar, University College of North Staffordshire, Keele, Staffs (August 19).

Junior Research Fellow in Pure Mathematics—The Registrar, The University, Sheffield (August 19).

Research Assistant (honours graduate in biochemistry or microbiology, or closely related fields with subsidiary biochemistry) in Microbiological Biochemistry to carry out research on problems of the regulation of metabolism in bacteria—The Secretary of University Court, The University, Glasgow (August 19).

Senior Lecturer (with outstanding qualifications and achievements in a relevant field of electrical engineering or physics) in Electromagnetism—The Assistant Registrar (Science), The University, Edgbaston, Birmingham 15 (August 19).

Electronics Designer (with a degree in physics or electrical engineering, or a comparable qualification) in the Department of Chemistry to collaborate with members of the teaching staff in designing and constructing electronic equipment to be used in research work in the Department—The Registrar, The University, Manchester 13 (August 21).

Principal of Thanet Technical College—The Clerk to the Governors, Education Office, Denemount, The Vale, Broadstairs (August 22).

Lecturer in African Anthropology—The Secretary, School of Oriental and African Studies, University of London, London, W.C.1 (August 31).

Research Assistant in the Department of Civil Engineering, to work with Dr. J. M. Zarek on problems of flow measurements under pulsating conditions—The Registrar, King's College, Strand, London, W.C.2 (August 31).

Senior Lecturer in the Department of Biochemistry (Sub-Department of Malting and Brewing)—The Assistant Registrar (Science), The University, Edgbaston, Birmingham 15 (August 31).

University Librarian; and Chairs of Agriculture, Archæology, Education, Zoology, Botany, Chemistry, Physics, Biochemistry, Mathematics, Geography, Pharmacy, Civil Engineering and Sociology in the University of Ife, Nigeria—The Registrar, University of Ife (Ibadan Branch), Ibadan, Nigeria (August 31).

Director of Research—Prof. A. C. Frazer, British Food Manufacturing Industries Research Association, Randalls Road, Leatherhead, Surrey (September 1).

Assistant in Zoology in the Department of Natural History—The Secretary, The University, Aberdeen (September 2).

Research Assistant (preferably male, with an honours degree in social anthropology or psychology) in the Department of Social Anthropology, to conduct an industrial study in the Midlands—The Secretary to the University, University of Edinburgh, Old College, South Bridge, Edinburgh (September 4).

Senior Lecturer (with a higher degree or equivalent qualifications and interested in promoting and leading research) in Mathematics in the Broken Hill Division of the University of New South Wales—The Agent General for New South Wales, 56–57 Strand, London, W.C.2, and the Appointments Section, The University of New South Wales, Box 1, Post Office, Kensington, New South Wales, Australia (September 8).

Research Associate (graduate in psychology) in the Department of Social and Administrative Studies, University of Oxford, for a project, sponsored by the National Science Foundation, Washington, concerned with perception—The Secretary, Barnett House, 40 Wellington Square, Oxford (September 10).

Lecturer or Assistant Lecturer in Agricultural Zoology at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (September 15).

Senior Lecturer or Lecturer in Physics at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 15).

Teaching Fellow (with an honours degree or equivalent qualifications) in the School of Mathematics, University of New South Wales, Australia—The Agent General for New South Wales, 56–57 Strand, London, W.C.2, and The Appointments Section, University of New South Wales, Box 1, Post Office, Kensington, New South Wales, Australia (September 19).

Chair of Veterinary Physiology—The Secretary to the University, The University, Edinburgh (October 1).

Analyst (preferably B.Sc. (Chemistry), and G.R.I.C., or equivalent qualifications) in the Department of Organic Chemistry, for duties mainly concerned with the operation and care of optical equipment including infra-red and nuclear magnetic resonance spectrometers—Mr. W. A. Wightman, School of Chemistry, The University, Leeds 2.

Assistant Experimental Officer (with a pass degree in biology (including zoology), F.I.M.L.T. or equivalent qualifications, and preferably some experience of histological techniques) in the Physiology Department to assist with histological investigations related to the endocrine research programme of the Department—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, quoting Ref. 61/22.

Forestry Officer (with an honours degree in forestry and a sound practical approach and ability to train and guide supervisory staff, preferably with experience in tropical forestry), to deal with all aspects of forestry work in Hong Kong, particularly with the preparation of management plans and in-service training—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/51/07/T.

Geologist (with at least a first- or upper second-class honours degree in geology, and preferably specialized in petrology) with the Falkland Islands Dependencies Survey for service in the Antarctic for two years—The Crown Agents, 4 Millbank, London, S.W.1, quoting Ref. M3C/53437/NF.

Graduate to participate in biochemical research on coagulation in normal human and human cancer tissue—Dr. W. A. Boggust, Department of Biochemistry, Trinity College, Dublin.

Graduate (with a degree in botany or zoology, and preferably previous experience in cytological work) for work in a section investigating cytogenetic effects of radiation—The Administrator, Radiobiological Research Unit, Medical Research Council, Harwell, Didcot, Berks.

Lecturer or Assistant Lecturer in Physics at Makerere University College, East Africa—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1.

Lecturer or Assistant Lecturer (particularly interested in petrology and mineralogy) in Geology—Prof. D. Williams, Geology Department, Imperial College of Science and Technology, London, S.W.7.

Lecturer (with special qualifications in pure mathematics) in Mathematics (Grade I or II)—The Registrar (Room 22, O.R.B.), The University, Reading.

Librarian to take charge of a technical library—The Director of Research, The Natural Rubber Producers' Research Association, 48–56 Tewin Road, Welwyn Garden City, Herts.

Microbiologist or Biochemist (recent graduate) for one year's sponsored research on antibiotics—Dr. J. G. David, 9 Gerrard Street, London, W.1.

Research Assistant (preferably with experience in cytology), to take part in a programme designed to study human chromosome abnormalities and associated disorders—The Secretary, Genetics Department, The University, Sheffield 10.

Research Assistant to take part in chromosome studies on human leukæmias and other forms of malignant disease using tissue culture techniques—The Administrative Officer, Mount Vernon Hospital, Northwood, Middlesex.

Research Fellow (with Ph.D. degree or equivalent research experience) in the Chemistry Department, to work in collaboration with Dr. J. J. Kipling on the carbonization and graphitization of high polymers—The Professor of Chemistry, The University, Hull.

Senior Research Associates (2) (preferably experienced electrical engineers or physicists with an electrical engineering background) in the Department of Physics for the development of the proton synchrotron—The Assistant Registrar (Science), The University, Edgbaston, Birmingham, 15.

FURTHER ADVANCEMENTS IN SPACE RESEARCH

COMMENTING on the latest Soviet achievement in space science, last year's president of the British Association for the Advancement of Science, Sir George Thomson, said: "If you have done a thing once it is not difficult to do it several times. It seems to me a cheerful Bank Holiday event, and we should thank the Russians for arranging it". After pondering these remarks they would appear less waggish and more profound than at first. The first remark is, however, rather naïve, for there can be no doubt that this second successful attempt to put man into orbit embraced more scientific 'things', with consequent results from which much can be gleaned, than were inherent in the first successful attempt, with Major Yuri Gagarin in the space-vehicle. The second remark, however, needed making. The news would be cheerful whether the feat was achieved by Soviet scientists, American scientists or those of any other nationality: for here, once again, is the manifestation of great triumphs for scientists, coupled with the heroism of another—this time Major G. S. Titov, of the Soviet Air Force.

The spaceship-satellite *Vostok 2*, 1961τ, launched from the U.S.S.R. at 06.00 hr. U.T. on August 6, carried the second man to travel in orbit around the Earth. The satellite, which weighed 4,730 kgm. excluding the final-stage rocket, was projected into an orbit inclined at 64° 56′ to the equator and having an orbital period of 88·6 min. Its height above the Earth varied between 178 km. at perigee and 257 km. at apogee. Its radio transmitters operated on frequencies of 15·765, 19·995, 20·006 and 143·625 Mc./s. *Vostok 1*, which carried Major Gagarin in the first manned orbital flight on April 12 (see *Nature*, **190**, 307; 1961), made one revolution about the Earth. *Vostok 2* made 17 revolutions, and, since the orbital period was such that the geographical track on the seventeenth revolution was almost identical with that on the first, Major Titov made his descent in the same region as Major Gagarin. Major Titov landed safely near Saratov, some 500 miles south-east of Moscow, after a flight lasting 25 hr. 18 min. The main object of this second orbital flight was to test the effects on a human being of a longer journey in orbit. Major Titov reported that his condition was excellent throughout his epoch-making flight, and the prolonged period of weightlessness appeared to have no ill-effects. He slept for 8 hr. and ate several meals, taking the food from tubes, as well as operating various manual controls in the satellite, observing the Earth from one of the three portholes, and sending messages to the peoples of the countries he passed over.

On this second occasion more details of experimental conditions were revealed, and even some preliminary results announced—an excellent and cheerful omen for scientific advancement on an international scale. Hitherto, far too much lip-service has been paid by Soviet and American political leaders to the ideal of sharing their scientific results; but little has so far accrued.

There can be no gainsaying the fact that the Soviet scientists are in the vanguard of space travel; but it does not follow that they are ahead of others in space research *in toto*. There are many who believe that the U.S.S.R., through their awe-inspiring achievements, are deliberately playing to the political gallery. It is obvious that their successes are enhancing the political prestige of the Soviets throughout the world, especially in scientifically and culturally backward and emergent countries. But it would be wiser for world leaders in policy to look on these successes in space-travel as the result of hard and inspired scientific endeavour made by scientists who are highly respected and encouraged by their political leaders.

Even in their own country, certainly outside it, Gagarin and Titov are presented to the public as great heroes, which they surely are. But it is essential to recognize that the real prime-movers in these fantastic feats are the scientists and technologists who, through their ingenuity and devoted effort, have made such feats possible. The lay public, both Soviet and millions of others, will acclaim the heroism of men such as Gagarin and Titov; but world leaders would be better advised to take heed of the words of Prof. Nikolay Barabashov, who said: "The general triumph of Soviet *scientists and engineers* consists in that they have created a spaceship controlled by man".

There are still too many otherwise intelligent people who grudgingly now admit that we have had science thrust upon us. They will continue that attitude at their peril, for this is the Age of Science, and, like it or not, we must do all we can to give moral, and especially practical, support to our scientists (*in all* branches). This is best done by learning and teaching more about science, for then shall we treat scientists for what they really are—world leaders in their own sphere, not 'backroom boys'.

Walter Bagehot said that: "Governments are only strong when public opinion is definable and decided". The strength of democratic Governments must now be enhanced by the support of a public opinion inspired by knowledge of, and greater respect for, science and scientists.

NATIONAL ORGANIZATION OF SCIENTIFIC RESEARCH

THE last report of the Council for Scientific and Industrial Research stressed the growing importance of the Council's influence on university research. This necessarily arises out of the Council's concern with the balance of research within and between the scientific disciplines, and its effort, at the request of the Advisory Council on Scientific Policy, to bridge any important research gaps which come to light and thus promote a healthy balance of research effort. It also arises as a counterpart of the Department's expanding programme of research grants and training awards, which are bound to affect university developments quite apart from the attempts of the Council to encourage co-operative effort, as, for example, in grants for the provision of nuclear reactors for training and research or by specia encouragement for research in certain fringe subjects, such as biophysics, geophysics, meteorology and oceanography, where the Council found insufficient research effort in the country.

Generally, the Council regards the balance of research effort as reasonable in the main streams of development within the chief scientific disciplines, though, to keep this effort adequate and to develop it flexibly, substantial and increasing resources must be given to research through existing channels. The Council is already prepared to make grants for longer periods than hitherto and help initiate projects which for one reason or another seem to require its specially extended support; but nevertheless, when university researches are well established, the Council considers that they are best supported from normal university funds, and the Council welcomes the action of the University Grants Committee in making arrangements for the universities to seek funds for the new quinquennium 1962–67, to continue researches which have been established with the aid of grants from the Department of Scientific and Industrial Research. The Council has already invited the universities concerned to consider whether they should seek funds from the University Grants Committee to carry on most of the research programmes receiving current grants and is discussing these arrangements with the universities.

In this situation, a statement on "Scientific Progress, the Universities and the Federal Government", issued last November in the United States by the President's Science Advisory Committee, to which Dr. Glenn T. Seaborg, chairman of the United States Atomic Energy Commission, made some reference in addressing the American Physical Society on April 26, on atomic energy research, is of particular interest. Dr. Seaborg did not discuss the Commission's programme of applied research; his address was rather on basic research in physical science, and before discussing the Commission's activities in basic research he quoted freely from the Science Advisory Committee's statement to illustrate his own fundamental philosophy of basic science.

The statement, which deals essentially with the problems arising in the advancement of science by basic research and the graduate education of scientists, stresses first the urgent need for scientific progress and for investment in science to that end, without, however, either overlooking the returns such investment also yields in the quality and humanity of our investigation or suggesting that scientific research and scientific education are the only kinds of learning that matter. It affirms unequivocably that basic research and graduate education go best together at every possible level, and equally it insists on the disappearance of the barriers between 'pure' and applied science. Basic research depends in the end on the imaginative powers and scientific skill of its practitioners, and partly because of this the apprentice scientist, even if his subsequent career were not attained in basic research, learns best in an atmosphere of creative research with the depth of understanding of a subject that only comes with such experience.

The President's Science Advisory Committee is under no illusions that this always obtains in the universities or in the Federal agencies, but it suggests that if a research field is to attract able young scientists, it generally needs roots in the universities. A scientific field which has no research life in the universities is at a grave disadvantage in recruiting new talent, nor can research be sustained without teaching, and it is always important for research institutions to maintain effective connexions with students. Not all basic research should or could be pursued in universities, but where it is done elsewhere the Committee believes that special efforts should be made to take advantage of its educational value.

The Committee thus came to consider the role of the Federal Government, which by 1957–58 was providing 70 per cent of the funds for research in American universities, three-quarters of which came from either health or defence agencies. The use of research contracts and research grants is then appraised, and, in spite of the high quality of much research, particularly in nuclear physics, carried out under Government contracts, the Committee regards the research grant, on balance and in the long run, as the better instrument for basic research. It points out, however, that the support of research projects does not, by itself, fully meet the needs of the Federal Government, and that no narrow or single instrument or method of action will serve the Government's purpose.

This appears particularly in considering the fields of science which are comparatively neglected and for which it is difficult for the universities to find funds or facilities. Like the Advisory Council for Scientific Policy and the Council for Scientific and Industrial Research in Britain, it suggests that such areas of scientific promise call for action by the central Government in initiative and support, and one such area instanced is oceanography. Nevertheless, the statement suggests that the greatest interest of the central Government is to see that university science is as strong as possible, and whether basic research and graduate education in the United States are adequate in quantity and quality depends primarily on the Government: either the Federal Government finds the policies and resources which permit the universities to flourish and discharge their duties adequately, or no one will.

The Committee recognizes that the American universities have themselves much to do and that they have been slow in finding effective ways of encouraging scientific research and training at all the new levels and in all the new ways that scientific advance makes possible. Graduate education is not so good as it should be, and new fields of study are ignored because they inconveniently cross departmental barriers. The Committee does not, however, share the view that Government support is necessarily subversive of academic freedom, though it recognizes its dangers; but it suggests that the most important single task of the universities is to maintain their own standards of freedom and excellence in this period of growing dependence on the State. In the United States, as in Britain, the main trouble in the universities is neither failure of understanding nor communication, but simply lack of means, and it is from this similar context that the recommendations of the statement derive their special interest in Britain at this juncture.

Some specific conclusions should, however, be noted; first, not only on account of their relevance to the general organization of scientific effort, but also equally for their bearing on the expansion of the universities and the colleges of technology. Stress is laid first on the support of excellence. It is of the first importance that national support for both research and teaching should aim at sustaining and reinforcing outstanding work wherever it may be found. Examination of the implications of this conclusion could go far to resolve some recent controversies, and it should be noted that the President's Science Advisory Committee also considers that additional centres of excellence are urgently needed, that graduate education should be expanded and include a genuine experience of research, and that it is important to attract a larger number of talented students to science as a career. Graduate education in science itself needs constant modernizing, and its financing should be continuously and flexibly reinforced, particularly by fellowships.

From what has already been noted it might be expected that the Committee would conclude that new fields of research and education need particular encourgement and that separate research institutions should be avoided wherever possible It is emphatic that in the absence of special considerations the university is the best place for basic research and concludes that new laboratories for special fields should be attached to the universities whenever it is practicable, and that universities should make full educational use of such facilities. It is interesting to note the Committee's opinion that scientists outside the universities can play a fruitful part in graduate education, and it is not only in the United States that there are opportunities demanding exploration and exploitation by the Government, by industry, by universities, and by colleges of technology.

Of the Committee's recommendations, some six were selected by Dr. Seaborg to express his own philosophy on basic research. First, there is the general responsibility. "In view of the growing importance of scientific research to National security and welfare, all parts of the National community should assume a greater responsibility for supporting, strengthening and expanding basic research in graduate education." Secondly, turning to Government responsibility, "Federal support for basic research and graduate education in the sciences should be continued and flexibly increased so as to support excellence where it already exists and to encourage new centres of outstanding work". Thirdly, "The Federal Government should continue and enlarge the practice now followed with great success in a few agencies of providing research support over long terms and for broad objectives". Fourthly, "The Government should strengthen its ability to establish general policies governing its support of basic research and graduate education at the universities". Fifthly, as regards the universities, "Universities should accept primary responsibility for ensuring that their growing partnership with the Government reinforces their freedom and excellence", and sixthly, and generally, "It should be a general basis of policy and action that basic research and the education of scientists go best together, that they are inseparable functions of the Universities".

These recommendations are cited by Dr. Seaborg to illustrate his own approach to basic research, an approach which has not been modified by his experience as chairman of the Atomic Energy Commission. He does not suggest that these are the only important recommendations of the report, but it is interesting to note how largely the Advisory Council of Scientific Policy in Britain appears to be guided by similar views. Nevertheless, the connexion between research and teaching is emphasized in a much more forthright manner than has been apparent in recent discussions in the United Kingdom, and the stress laid on excellence gives no support for the mediocrity and triviality which Sir Eric Ashby and others have criticized.

If this report, therefore, contains much that is of interest to the University Grants Committee and the Robbins Committee also, as well as to the Ministry for Science, Dr. Seaborg's examination of the policies and programmes of the Atomic Energy Commission in the light of these findings is of particular interest in the context of adjustment of Britain's scientific effort with which the Advisory Council on Scientific

Policy is concerned. Dr. Seaborg points out that the budget of the National Science Foundation has already been increased by some sixty-five million dollars to implement some of these recommendations, and two-thirds of this is for support of basic research in the sciences and to improve research facilities. Further, he stresses the close co-operation and exchange of information that already exist between the Commission and the other four Federal agencies that disburse about 90 per cent of Federal funds for basic research. There is some reason for concern as to whether that liaison is sufficiently effective in Britain, and this may be one reason for the misgivings that have been openly expressed as to the deployment of our scientific man-power. At the Baird Memorial Lecture in Glasgow, in May, Dr. S. C. Curran suggested that scientific advance in some fields was hamstrung by the excessive effort being made in such fields as nuclear energy, for example, and on the other hand, the existing relations between the Atomic Energy Authority and the Central Electricity Generating Board appear to offer at least some possibility of duplication of effort. It is by no means clear that the Board's new nuclear laboratory on which £1 million is to be spent, with a staff of 250–500, can do anything which could not be done with the Authority's existing plant and research teams. While there are advantages in the decentralization of nuclear research and engineering, they will not be realized without a careful review of organization and some paring of the effort for which the Authority has hitherto been receiving a consulting fee of £300,000 from the Board.

Dr. Seaborg's remarks about the Atomic Energy Commission's relations with the National Science Foundation and with the universities are of special interest at the present time. Under an agreement with the Foundation, the Foundation takes care of the Commission's projects which involve support of university research and training reactors, but while the universities are part of the foundation on which the United States nuclear energy programme is built, the pattern of arrangements varies widely. At Brookhaven National Laboratory, for example, which is managed for the Commission by Associated Universities, Inc., some 170 scientists are engaged in research and about 300 more from university faculties spend considerable time each year at the Laboratory on research projects. The Argonne National Laboratory is operated under a contract with the University of Chicago, but the thirty-one constituent schools of Associated Mid-West Universities play a vital part in the Laboratory's programme with more than 100 postgraduate research workers, while the Laboratory also operates the International Institute for Nuclear Science and Engineering. Again, at the Lawrence Radiation Laboratory in the University of California, Berkeley, where about 250 graduate workers are employed, basic research is undertaken by faculty members on a part-time basis and by full-time non-academic personnel. Again, at the Oak Ridge National Laboratory, the Union Carbide Nuclear Co. co-operates in making the facilities available to universities, for example, through the Oak Ridge Institution of Nuclear Studies, comprising 39 universities in the south.

Dr. Seaborg gives some figures to indicate the extent of the Commission's research effort. At the end of the past fiscal year, the Commission had more than 900 contracts totalling more than thirty-six million dollars for unclassified basic research in the physical and biological sciences with some 162 educational institutions. Some 330 schools have been assisted with grants totalling 18·5 million dollars, and loans of nuclear materials valued at eleven million dollars and about 1,000 fellowships have been awarded. Basic research supported by the Commission in the physical sciences is mainly in physics and mathematics (including high- and low-energy nuclear physics, computor research and mathematics), metallurgy and related sciences; chemistry and controlled thermonuclear research.

Dr. Seaborg referred to the way in which the Commission is seeking to strengthen research in the metallurgy and material sciences throughout the country, and also to the existence of areas where imaginative contributions of the highest creative type were needed to advance the country's welfare not simply in the nuclear energy programme but in such fields as the long-range transmission of electric power, long-range prediction of weather, the desalting of sea-water, and the application of biophysics and biochemistry to the whole problem of living matter. He was prepared to consider allowing the Commission's National Laboratories to contribute to the solution of such problems even if this went beyond their present functions.

The choice of method or organization is bound to be influenced by the objective or subject of a research project and that alone is sufficient reason for requiring variety and flexibility in the organization of research, whether fundamental or applied. While the points made by the President's Science Advisory Committee and by Dr. Seaborg are not new, they direct attention to first principles to which full regard should be paid alike by the University Grants Committee in considering the expansion of university education and by the Advisory Council on Scientific Policy and the Council for Scientific and Industrial Research in guiding the deployment of Britain's research effort. Furthermore, the extent to which that expansion and research effort are interlocked points to the importance of some co-ordinating authority at a higher level, if frustrations or waste are not to occur. Both through its research grants and its post-graduate training awards the Department of Scientific and Industrial Research cannot now help strongly influencing university development or even policy, however carefully it may seek to avoid infringing academic influences. For example, after the Department's last annual report was issued a grant of £750 was announced towards a project to which the University Grants Committee and the National Institute for Research in Nuclear Science was also contributing.

It is important that Britain's organization for the support of research should be flexibly and also effectively co-ordinated; the choice of project poses difficult problems also. With whatever justice it may be argued that our present expenditure on nuclear research, whether through the Atomic Energy Authority or more generally, is excessive, those who so argue are usually concerned at the neglect of a particular field. Dr. S. C. Curran, for example, was concerned at our neglect of space research and lack of a satellite programme. Here again we are concerned with a field calling for particularly costly equipment, but Sir Harrie Massey, in a recent statement referring to the growing interest in space research in British universities, suggested that such research could be considerably extended without distorting our scientific effort. This, he thought, was not a narrowly specialized field of work, but required more facilities, and collaboration in a European organization should not preclude a separate programme of research in Britain.

At the anniversary dinner of the Biochemical Society on March 29, Lord Hailsham said that it was important that not merely the structure but also the philosophy of our present arrangements for the organization and encouragement of research should be brought home to scientists. That is true enough, but it is no less important that the magnitude of Britain's effort should be seen to be in proportion to national needs, and it is from misgivings as to the scale of our effort that much of the present malaise arises. That is, of course, a main theme in the pamphlet, *Science and the Future of Britain*, issued in March by the Labour Party, but it is not simply a party political issue; it is fostered also by procrastinations and petty-mindedness that, as in such matters as scientific libraries, have already squandered resources in both finance and man-power.

Lord Hailsham quite rightly insists that the scientific planning of our research effort must be done by scientists themselves. Ultimately they must decide on the project and the means by which it is to be secured. That, however, ultimately turns on the availability of resources, and while, as Lord Hailsham said, the function of the Government is to see that the necessary research was proceeding and that its results were being applied, the fact that for the most part Government acts here indirectly through encouraging science in the universities, stimulating industrial research and organizing research institutes in fields where necessary, does not affect the fundamental issue of the availability of adequate resources.

The Minister for Science appears to be satisfied that the Research Councils, the Atomic Energy Authority, and the Advisory Council on Scientific Policy provide him with an adequate advisory structure, though some questions of ministerial relations could well be asked. He referred on this occasion particularly to the relations between the Department of Scientific and Industrial Research and the Medical Research Council and the University Grants Committee; the value of independent sources of finance for research is indisputable. Nevertheless, we come back once more to the question of the scale of the research effort in Britain. If the existing structure has proved its ability to prevent dissipation of our research effort on projects which are not easily justified in relation to viable national needs, it is the more important that its scale should be commensurate with real needs rather than political convenience. It is at the magnitude of our effort as well as at its deployment that Lord Hailsham should be looking, and making sure that departmentalism is no more an obstacle at ministerial level than in universities or elsewhere to the full exploration of new opportunities or a cover for waste and conservatism. Further, the implications of the relation between teaching and research also deserve examination, and if the President's Science Advisory Committee is right in its conclusion, some recent developments such as that at the Radar Research Establishment call for examination by the Minister for Science from that point of view if precious resources of man-power and equipment are to be used to the fullest advantage.

A REFERENCE BOOK FOR BIOCHEMISTS

Biochemists' Handbook

Edited by Dr. Cyril Long. Consultant Editors: Prof. Earl J. King and Prof. Warren M. Sperry. Pp. xxii + 1192. (London: E. and F. N. Spon, Ltd., 1961.) 168*s*. net.

THIS handbook caters for fairly big-handed biochemists: it consists of almost twelve hundred pages of techniques, tables, facts, figures and references on a very wide range of biochemical topics, and includes the contributions of 171 authors.

The book is divided into six main sections. Section 1, called "Chemical Data", deals in the main with commonly used biochemical techniques like spectrophotometry, chromatography and manometry, but contains, in addition, information about isotopes, an excellent account of volumetric analysis (with many tables of buffer solutions and a very full list of acid dissociation constants), a brisk contribution on organic chemical nomenclature, and some useful data on the composition, structure and analysis of polysaccharides.

Section 2, "Data on Individual Enzymes", deals with nearly three hundred enzymes, which are arranged in groups according to the type of reaction they catalyse—hydrolysis, transfer, dehydrogenation, etc. Then follow a hundred pages on "Metabolic Pathways", giving a condensed and up-to-date account of important reaction schemes. This chapter is intended primarily for biochemistry teachers.

Section 4 (pp. 637–936) is called "Chemical Composition of Animal Tissues and Related Data". Presented mainly in the form of tables, this section takes us tissue by tissue through one, and sometimes several different species of animal to give an extraordinary wealth of data (46 pages are given to the composition of blood alone). Section 5 concerns itself with the chemical composition of plant tissues, and is considerably shorter than the previous chapter despite having "been given somewhat greater prominence than is customary". After a brief introduction on plant nomenclature and classification (a subtle 'dig' at biochemists who are all-'chemist' and no 'bio-' ?), subdivisions are made between one type of chemical constituent and another. Individual presentations vary, but in general the compounds, with their chemical characteristics and natural sources, are listed with appropriate references, in tabular form. The book ends with a short section on "Physiological and Nutritional Data", which is rather on the fringe of biochemistry and has a fairly strong medical bias.

If, as the authors state in the preface, this book is meant to serve as a source of material for research biochemists, criticism could be levelled at some sections. The chapter on enzymes is so condensed and indigestible that probably both specialist and non-specialist alike will prefer to reach for 'Dixon and Webb'. One or two accounts of enzymes do not cover the subjects fully, and tend to be a bit unsatisfying because the selection of data has been too stringent. (The account of β, 2–1 fructanases, for example, does not even mention the work of Bacon and Edelman.) Also, in Section 1, perhaps it might have been a better idea in a book of this kind to have concentrated more on drawing up fuller lists of data (R_F values of more compounds in the chapter on paper chromatography, for example) rather than to have written so much on theory and technique, which are covered extensively in more specialized text-books. When the book concentrates on condensed information in the form of tables, figures and references (which is most of the time), it is excellent.

There are, however, one or two misprints; on pp. 953–4, '*Hordenum*' appears four times: it should be *Hordeum*. '*Liriodendro*' is printed instead of *Liriodendron* on p. 951. On p. 114 ribonucleose is written for ribonuclease, and on p. 515, the word 'succharides' might cause some hilarity.

The main strength of the book lies in its references, and in this respect alone it more than justifies the authors' claims that it should be regarded primarily as a source of biochemical material. If information is sought, one is almost certain to find it in the *Biochemists' Handbook*—and even if it is not there the references will indicate the source.

D. RECALDIN

REVIEWS OF GENETICS

Principles of Genetics

By Prof. Eldon J. Gardner. Pp. vii+366. (New York and London: John Wiley and Sons, Inc., 1960.) 60*s*.

Principles of Plant Breeding

By Prof. R. W. Allard. Pp. xi+485. (New York and London: John Wiley and Sons, Inc., 1960.) 9 dollars; 72*s*.

Genetic Research

A Survey of Methods and Main Results. By Prof. Arne Müntzing. Pp. 345. (Stockholm: LTs Forlag, 1961.) n.p.

THESE three books are written for different readers. The first is intended "primarily for the college student taking his first course in genetics" and presents the fundamentals of genetics accurately in a straightforward and readable manner. The first eight chapters are concerned mainly with Mendel's experiments, the mechanics of the transmission of hereditary units, their interaction and the ways in which they can be located on the chromosomes by studies of linkage and recombination. Then, among other topics, the author deals with structural alterations of chromosomes, sex determination, mutation and alleles and compound loci. He indicates some present trends in chapters on physiological genetics and population genetics. One of the pleasing features of the book is the skilful way in which experimental results from both higher and lower organisms are woven into the text; and with equal facility, the student is given a hint of the usefulness of statistics and chemistry in modern genetics. It is a pity that the book is so expensive.

Prof. Allard's book is not greatly different in scope from some of the others on this subject. The reader is assumed to have a knowledge of cytogenetics, and emphasis is placed on principles of plant breeding rather than on breeding procedures for particular crops. After a brief discussion of patterns of evolution in cultivated plants and a general account of their reproductive systems, the author separates self-pollinated and cross-pollinated crops and, in each, in turn, deals with the genetic basis of breeding and with breeding methods. In my own opinion, Prof. Allard loses some possible clarity by not considering the roles of genotype and environment in continuous variation apart from mating systems. One of the most admirable sections of the book is that on breeding for resistance to disease, in which the interactions of host and parasite are very fully discussed; unfortunately, resistance to virus diseases is completely overlooked. The author writes in a vigorous and lucid style, but at times the subject-matter is condensed to the point of oversimplification; contrary to the author's statements, cultivated potatoes are, regrettably, classified into several species and many diploid edible bananas are sterile. Several Latin names are wrongly quoted and there are other printing errors that could well be corrected in subsequent printings.

Prof. Müntzing attempts in his book to cover the whole field of pure and applied genetics for the benefit of "everybody working with living material or teaching biology". Indeed, in slightly more than 300 pages, he deals with more topics than are included in the two other books under review. The reader will find chapters on all the traditional aspects of genetics —Mendelism and the developments therefrom, the structure of chromosomes, speciation, plant and animal breeding and eugenics. The facts are described accurately and clearly, but in order to cover so much ground many behaviours have to be treated in a somewhat cursory way; for example, the topic of self-sterility in plants is dismissed with a brief account of gametophytic incompatibility; a short description of the biochemical genetics of eye colours in *Drosophila* serves as a picture of the gene-controlled formation of pigments in plants and animals. Nevertheless, the account of genetical investigations in bacteria and viruses and the discussion of the nature of the gene are masterly condensations of available information. I was left with the impression that the book is too advanced for the amateur geneticist but, without a more extensive bibliography, falls short of being a satisfactory text-book for the intending professional. It is an unfortunate compromise. The book is well reproduced with excellent illustrations and diagrams. That the text is a translation is still evident; apart from clumsy sentences, words are sometimes wrongly used: "bacteriophage . . . creeps . . .", "electron microscopes . . . large power of dissolution".

KENNETH S. DODDS

PROGRESS IN CHEMISTRY

Modern Aspects of Inorganic Chemistry

By Prof. H. J. Emeléus and Dr. J. S. Anderson. Third edition, revised and reset. Pp. xi+611. (London: Routledge and Kegan Paul, Ltd., 1960.) 35*s*. net.

Radioactive Tracers in Chemistry and Industry

By Pascaline Daudel. Text augmented and revised by the author. Translated by Dr. Ulli Eisner. Pp. xi+210. (London: Charles Griffin and Co., Ltd., 1960.) 36*s*. net.

Annual Reports on the Progress of Chemistry for 1959

Vol. 61. Edited by Dr. R. S. Cahn. Pp. 476. (London: The Chemical Society, 1960.) 40*s*.

THE book by Emeléus and Anderson is now so well known that any detailed description of its contents is superfluous. The new edition has been carefully revised, new sections have been added, and some of the text in earlier editions which is now less important has been omitted, so that the size of the book has not been substantially increased. This is important for two reasons. First, the very reasonable price of a book of this character has been maintained. Secondly, the amount of material which can be dealt with in lecture courses and read by students is limited, and while a book of this size provides something which an average student may be expected to master, a larger book would be less acceptable.

Among the many new topics dealt with, mention may be made of a short but instructive account of ligand field theory, the chemistry of ferrocene and related compounds, sulphur nitride and its derivatives, and much new material in the chapters on co-ordination compounds. The last subject, with the main emphasis on chemistry, has always been a notable part of the book, and I know of no other account which can match it for clarity and completeness. In most of the other sections which were dealt with in previous editions, such as the boron and sulphur hydrides, significant new material has been added. The whole book is worthy of the highest praise from the point of view of the selection of material and also for its treatment.

One or two minor matters which were noticed are mentioned here not for criticism but in the hope that the authors may see their way to consider them in a future edition. I think the rather short section on molecular orbitals, which is quite largely drawn on in later parts of the book, will prove difficult to many students. The symbols for hybrid states on pages 61 and 69 are not clearly defined. If another four or so pages were added to this section it could be made clearer. The short table of dissociation energies on page 101 seems to be based on a quoted source of 1947, and it might have been pointed out that some of the values are still doubtful. I did not notice any reference to 5-valent manganese, and the section on metal hydrides on page 416 should be brought up to date by inclusion of the new preparation of cuprous hydride; the rather sceptical treatment seems now scarcely justified. The higher oxide of sulphur described on page 473 has been shown not to exist. In some cases the statement that "the structure is unknown" is misleading; there is little doubt, for example, that iodine dioxide is I_2O_4, since it is diamagnetic. The new formula for graphitic oxide does not seem to be mentioned. On page 52 bivalent americium is mentioned but on page 597 it is said not to exist. It now seems that N_2O_3 is $ON{\cdot}NO_2$ rather than a compound with an oxygen linkage as shown on page 466, and it is scarcely correct to say on page 468 of hyponitrous acid that "the structure has not been determined", since the dipole moment of its esters clearly indicates a trans-configuration. These are all small matters which little affect the accuracy of the book as a whole and the obvious care with which the information has been sifted.

The subject of radioactive tracers is now so important both in chemical laboratories and in industry that the short account of it by Daudel is welcome. The biological applications are not included. The text is clear and easy to read and outlines of laboratory methods are given which could enable a reader to judge whether a method is likely to be of interest in his field or not. This applies particularly to the industrial applications, since there is obviously a large field here which may not be very well known to those engaged in technical processes. The sections are followed by detailed references to the literature which seem to be brought up to the year 1955. The series of reports now being issued by the National Academy of Sciences, Washington, under the auspices of the National Research Council, will provide further information. It seems to me that this modest book should find a place in every works laboratory.

The *Annual Reports* issued by the Chemical Society continue to provide, in a commendably small volume, a survey of progress in chemistry which for compactness and completeness is unrivalled. All chemists have cause to be grateful to those who participate in the difficult task of surveying the fields of knowledge which they are so well fitted to traverse. The more recent policy of attempting to cover, however briefly, all the important work of the year, rather than to provide reviews of selected parts of it, which is possible in the case of inorganic and organic chemistry, seems on the whole to be a good one. In physical chemistry it is scarcely possible, and selected topics are treated from year to year, the material which has accumulated in the interval being brought together. The book is one which every chemist and every advanced student should have, and its relatively low price puts it well within his reach.

J. R. PARTINGTON

MEGALITHIC TOMBS OF FRANCE

The Prehistoric Chamber Tombs of France

A Geographical, Morphological and Chronological Survey. By Glyn Daniel. Pp. xx+282+32 plates. (London: Thames and Hudson, Ltd., 1960.) 70*s*. net.

TO win appreciation for some phase of antiquity on the strength of modern excavations is far easier than what has been undertaken here—where the antiquities concerned have been known for centuries, until only yesterday often excavated badly, and celebrated in a literature in which perverse and obsolete terminologies have run riot. Dr. Daniel, supported by his wife, and with backing from many quarters as well as friendly French co-operation, has for long been working towards a systematic account of the megalithic and related stone tombs of France, their form and contents, and their placing in the frame of European prehistory in the third and second millennia B.C., to which in general they belong. This book, by no means his first study of megalithic structures, is his best so far. It is not too hard to read. Though he as well as others will certainly follow it with further work, yet he has broken the back of the subject's principal difficulties. These, above all in classification and terminology, were formidable in a manner made peculiarly acute by the history of this study among the French, which he traces in a sympathetic chapter. The core of the work then comes in the 150 pages describing the tombs themselves, using, from the multitude of some 6,000 recorded, the numbers intelligible to-day in each of seven main regions: the North, Brittany, the Centre-West, the South-West, the South, the Centre, and the East. To visit these or their remains, perhaps 1,500 of them, the Daniels have travelled, tramped, recorded and tramped again, cheerfully making friends by friendliness and amassing information; the mass is here given to us critically sifted and classified, and steadfast readers will find that it makes sense. The steadfastness is of course put to some strains, though the worst is not the terminology, because Dr. Daniel has worked so hard to straighten the tangle of both French and English theoretical and descriptive terms. The most unnecessary is his assumption that readers can do without any sketch of the background in Mediterranean and Iberian lands whence French tomb-building was initially inspired. For of his two main categories, passage-graves come all from Iberia, whether Atlantic-wise to Brittany or Mediterranean-wise to the South, while gallery-graves may now be Iberian too, now adapted in the South from rock-tombs in Sardinia. One is supposed to have looked up classes of pottery, too, such as Bell-beaker or Polada, elsewhere beforehand.

The same applies to the chronology. For nearly all the dates used are borrowed, without reason for them given, from other lands. In the second millennium, most are slightly too low; in the third, the whole scheme may need drastic raising to meet carbon-14 determinations, which began to invade the megalithic field just when the book was finished. Yet this again means that it is timely: it tells us *what* the pattern is that carbon-14 may alter; and without that, the new method would have looked like making confusion worse confounded. The book deserves a serious welcome.

C. F. C. HAWKES

MATHEMATICAL DELIGHT

The Language of Mathematics

By Dr. Frank Land. Pp. vii+264. (London: John Murray (Publishers), Ltd., 1960.) 21*s*. net.

IN an essay which formed part of the symposium "The Quality of Education", Dr. J. Bronowski put forward in 1947 the thesis that mathematics was a language. For many people this statement would seem to be an exaggeration if their remembrance of the subject was little more than a series of tricks designed to get the 'right answer' by the application of routine processes. Yet a little reflexion will show clearly that some, at least, of the essential constituents of a language are certainly present. There is a vocabulary (which like most may be merely remembered); there is certainly a grammar, the rules of which must be rigidly followed. It is a necessary means of communication about the real world, and here the limits need not be set within national boundaries. What has been so long neglected is the æsthetic appeal of this discipline, rigid in its logic but thrilling in the power of its 'literature' and its 'poetry'. The past thirty years has been a time of amazing development at the frontiers of knowledge in this field, but there has also been astonishing progress in the methods of teaching at all stages from the primary school onwards.

Dr. F. W. Land, the professor-elect in education at the University of Hull, carried out an investigation into the "attitude and attainments of 2,000 grammar school leavers", and the study revealed the need to present the fundamental principles of mathematics in a new light for the mature reader. The Shell International Petroleum Co. made it possible for Dr. Land to embark on this project, and the present volume is his very successful attempt to satisfy this need. The book is published in two bindings, and there is now available a set of exercises which will add to the profit of those who approach it with serious intentions.

It is in every respect a delightful book; merely to turn its pages is an attractive occupation and the reader is drawn again and again to browse, to ponder and then to read with understanding. Little in the way of prior knowledge or acquired ability in mathematics is necessary from those who begin. If they are prepared to think as they read, the author's enthusiasm and clarity of expression, supported by Margaret Clark's beautiful illustrations, will carry them along. I read it at a single sitting and have no hesitation in saying that it should form part of the general studies course in every sixth form, as well as being a source of pleasure and profit to every intelligent adult.

The first six chapters are devoted to arithmetic, but they range far outside the limits of commercial calculations, which is all that so many students know about the concept of number. There is an attractive treatment of the problems of the calendar, and a careful discussion of the British system of units. Then come four chapters concerned with the generalizations which we know as algebra, though here again the range is wide and the treatment exciting; the use of graphs leads to such unexpected considerations as the whirls on the shell of *Nautilus* and the florets in the heads of Compositae. The second fundamental concept of mathematical thought, the concept of space, includes within its two chapters much that is traditional in geometrical teaching, but map projections and the four-colour problem, some elementary topology and the applications of Euclid's golden section, show how Nature has her laws which man may understand and use though he cannot control them. The final chapter, on statistics, is perhaps the only part of the book in which considerable demands are made on the reader, for though the treatment of normal distribution is easy and interesting, the development of correlation and the use of scatter diagrams may cause some readers to put aside the last few pages for 'another day'.

A tribute is due to Will Carter, who designed the volume; his collaboration with the printers has produced a book of lasting value and immediate appeal. The proof reading was carefully done for there are few misprints. Such blemishes as the statement (p. 171) that the three angles of a triangle "add up to a straight line", and the drawings (p. 156), which are neither isometric nor perspective, can easily be removed with a second edition, and this should soon be needed. The book ought to be in every public library in the country—or rather its place on the shelves should permanently be empty.

W. J. LANGFORD

FUTURE OF NUCLEAR PHYSICS IN AUSTRALIA*

By Prof. E. W. TITTERTON, C.M.G.

Research School of Physical Sciences, Australian National University, Canberra

RESEARCH into nuclear physics nowadays falls into two main categories—what I shall call low-energy and high-energy nuclear physics. In general terms I would define low-energy nuclear physics as embracing the energy-range for bombarding particles between zero and some 50 MeV. Under these conditions the incoming bombarding particle is of sufficiently long wave-length to see the target nucleus as a whole; that is, we are able to study the properties of all nuclei available to us. At higher energies, up to the maximum presently available from accelerating machines, which is 25,000 MeV. or 25 GeV., the wave-length of the incoming projectile is small compared with the nuclear size and the interaction is no longer with the nucleus as a whole. To the bombarding particle, all nuclei look the same—just an assembly of neutrons and protons. The interactions are nucleon–nucleon interactions, and tell us little about nuclear structure; among other things, they lead to the production of mesons and strange particles which are associated with nuclear force fields and which, therefore, are of great importance.

To see what the Australian role in these fields is likely to be in the future, it is perhaps easiest to survey, first of all, the present position. Early in March this year, a major conference on nuclear physics was held in the Australian National University, Canberra. In many ways it marked a turning-point for Australia—partly because it was held to coincide with the final stages of erection of a new accelerating machine at the Australian National University, and partly because, for the first time, outstanding overseas research workers felt it to be worth while to travel to Canberra especially to take part in the meetings and learn what was going on in the field in Australia. In the four days of the meeting, virtually all current work in Australia was reviewed.

Sixty-two papers were read, of which twenty-eight came from the Australian National University, eleven from the University of Melbourne, six from the University of Sydney, four from the University of Adelaide and one each from the Universities of Tasmania and Western Australia; the remainder were papers given by overseas visitors. The vigorous growth of the work in the country can be judged from the fact that at a similar conference organized by the Australian National University in 1958, the total number of papers presented from all sources was twenty-eight; the output of work increased considerably in the three-year interval.

In Table 1 a summary is given of work going on in the Australian universities. It will be seen that of the ten universities, seven have some work in the field, if one includes work in cosmic-ray physics. In recent years, as is shown, there has been a very strong development of theoretical nuclear physics in the country. This came about partly because of the intrinsic importance of such work, but more importantly because big capital investment is not required and, apart from computer time, expenditure for theoretical work is limited to salaries and the provision of office accommodation. The situation is quite different in the case of experimental nuclear physics, especially if one leaves aside the rather specialized work in cosmic rays. Worth-while work in nuclear physics necessitates big capital expenditure for laboratories, accelerating machines, detecting equipment and data processing, while considerable staffs of technical assistants are required to maintain the very complicated equipment and aid the experimental work. Because of this heavy demand on money and on staff, such work is pursued only in the University of Melbourne and at the Australian National University. The former has four accelerating machines—one variable-energy cyclotron capable of yielding protons up to a maximum of 12 MeV., two electrostatic generators capable of voltages up to 800 KeV., and an electron synchrotron yielding a peak energy of 18 MeV. Of these, the cyclotron is a major experimental tool, and has, for some time, been turning out important experimental results.

Table 1. Summary of Nuclear Research Work now in Progress in Australian Universities

University	Scientist in charge	Type of work
Australian National University	Sir Mark Oliphant	Particle (high-energy) physics including the design and construction of a 10,000-MeV. proton accelerator.
	Prof. K. J. LeCouteur	Theoretical work in nuclear physics.
	Prof. E. W. Titterton	Experimental work in nuclear physics.
University of Melbourne	Prof. C. B. O. Mohr	Theoretical work in nuclear physics.
	Prof. D. Caro	Experimental work nuclear physics.
	Dr. V. D. Hopper	Experimental work in cosmic-ray physics.
University of Sydney	Prof. H. Messel	Theoretical work in cosmic rays.
	Prof. S. T. Butler	Theoretical work in nuclear and particle physics
	Prof. C. B. McCusker	Experimental work in cosmic-ray physics.
University of Adelaide	Prof. H. S. Green	Theoretical work in nuclear physics and high-energy physics
University of New South Wales	Prof. J. M. Blatt	Theoretical work in nuclear physics.
University of Tasmania	Dr. A. G. Fenton	Experimental work in cosmic-ray physics
University of Western Australia	Dr. H. Thies	Certain photonuclear experiments.

---

* Substance of the presidential address delivered to Section A of the Australian and New Zealand Association for the Advancement of Science meeting in Brisbane, May 30, 1961.

At the National University there are four accelerating machines, including a 1,200-KeV. Cockcroft–Walton accelerator, an 8-MeV. cyclotron, a 33-MeV. electron synchrotron and a 12-MeV. tandem electrostatic accelerator completed in May of this year. Nearing completion is a 2-MeV. Van de Graaff generator which will serve in the dual role of an accelerator in its own right and also as an injector to allow helium ions to be accelerated in the tandem. Under construction there is a 10-GeV. (10,000 MeV.) proton synchrotron which will be powered by a giant homopolar generator capable of currents in excess of a million amperes.

This last machine, which is being constructed by a group working under Sir Mark Oliphant, incorporates novel features, many of which were essential to allow the machine to be built with the funds and staff available. Thus an orbit of about 30 ft. diameter was chosen, and this requires restraining magnetic fields at the orbit of 80,000 gauss or so. Such fields cannot be achieved with an iron magnet, and an air-cored system was therefore chosen. This necessitates currents of peak value near to 1½ million amp., requiring a homopolar generator with liquid metal brushes as power source. The penalty which one pays for this 'poor man's' high-energy accelerating machine is a low pulse-rate—approximately 1 pulse/10 min. In competition with overseas machines in the same energy-range, where pulse-rates are one every 1 or 2 sec., this means that there is a severe intensity disadvantage. The field of experimental work in high-energy physics with this machine when it is completed will therefore be limited.

The homopolar generator, however, will be a most useful power source for other purposes—for example, certain investigations in the plasma physics field.

This accelerator of Oliphant's is likely to be the only one built in the high-energy field in Australia. The reason is that investments now being made for high-energy accelerators of 10 GeV. and upwards overseas are in the range of £A.10 million–£A.100 million with similar sums of money per installation required for ancillary experimental equipment. Moreover, the teams of people required to build, operate and use such equipment approach, for one installation, the entire physics staffs of the combined Australian universities. It is therefore clear that in the future, Australia will be unable to compete with the big nations in the field of high-energy experimental particle physics. Some work can go on profitably in cosmic-ray physics, but this is likely to be on the more geophysical aspects of the subject rather than in the nucleon–nucleon interaction field where, again, the intensity advantage and flexibility of experimental arrangement make an accelerating machine the highly preferable tool. There is no reason, however, why effective theoretical work in the high-energy field should not be carried out in Australia, and it is encouraging to note that small groups are already in being in Adelaide, Canberra and Sydney.

To return to the field of low-energy nuclear physics, I should remark that, in addition to the work going on in the universities, there is a group at the Australian Atomic Energy Establishment, Lucas Heights, Sydney, whose task it is to make certain nuclear measurements of importance to the atomic energy programme. It is called the Reactor Physics Division, and was responsible for the nuclear measurements made in Australia's first reactor *Hifar*, and it has now acquired a smaller reactor named *Moata* for the needs of its own work. Most of its work is of an applied nature, but some of its studies in neutron physics, for example, neutron diffraction, will be of wider interest.

A joint Universities–Atomic Energy Commission organization called the Institute for Nuclear Science and Engineering is now beginning to operate effectively. It has offices and laboratories at Lucas Heights, and members of staff of any Australian university desiring to use the unique facilities at Lucas Heights are encouraged to go and work there. Although the Institute will be able to support some nuclear physics work, this is likely to be a small part of its overall programme since the nuclear problems which can be tackled using a fission spectrum in a reactor are limited in variety. It is to be expected that most experimental effort will go into chemistry, metallurgy, solid-state physics, biology and medicine, and perhaps geophysics.

It will be apparent, then, from this brief survey that the future of nuclear physics in Australia will reside, on the experimental side, in the fields of low-energy nuclear physics with some peripheral activities in cosmic rays and plasma or thermonuclear physics. But there is no reason why, on the theoretical side, work should not range over the whole field providing always that our theoretical colleagues give adequate backing to the low-energy experimental programmes going on in the country.

It was for reasons of the type outlined above that in considering the future programme at the Australian National University we chose to make a major investment in the field of low-energy nuclear physics by building a tandem electrostatic generator which is the most flexible and sophisticated tool available to the experimenter at the present time.

But, first, I want to offer reasons why I believe it is essential to have at least two flourishing schools of experimental nuclear physics research in the country.

The training received by a graduate in going to a Ph.D. degree in nuclear physics is about the broadest I know. The student must learn to handle a wide variety of equipment—electronics, both valve and transistor, vacuum physics, thin film preparation, accelerating machines, a wide variety of light and ionization detectors, multichannel memory storage devices, data processing systems and so on—merely as tools for doing the job of an experiment in nuclear physics. Then he must have an adequate understanding of the basic theory to be able to interpret the results properly. I am inclined to agree with Dr. Louis Rosen, a recent visitor to our Laboratory from the U.S. Atomic Energy Commission, who said: "We find that training in nuclear physics is the best a physicist can get. Such men have great breadth of outlook and a remarkable diversity of knowledge. They can turn their hands at any time to solve difficult problems of technology which continually arise in the country".

This point was demonstrated most effectively during the War, when it was found that the nuclear physicists recruited from the universities, both in the United Kingdom and the United States, rapidly took over the leadership in the development of radar and operational research methods before going on to develop the nuclear reactor—the power source of the future—and the uranium isotope separation methods required to obtain the highly fissile materials, plutonium and uranium-235, necessary to manufacture the nuclear bombs which finished the War.

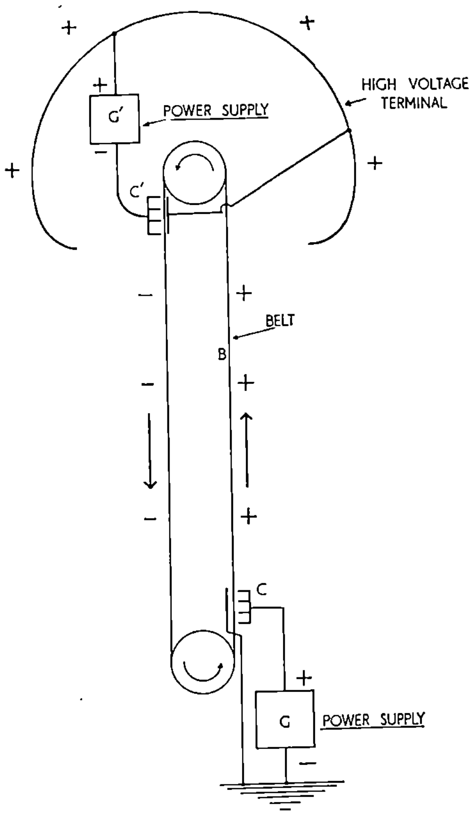

Fig. 1. Schematic diagram of the original (single ended) Van de Graaff accelerator. Charge from a power supply *G* is sprayed into a moving belt *B* and carried to a hollow spherical terminal *T* where it is removed. Charge of the opposite sign can be sprayed into the belt from the power supply *G′* and carried from the terminal if desired. The practical voltage limit to such a machine is 6–7 million volts

Out of these nuclear developments has grown the biggest industry in the world—the nuclear or, as it is popularly called, the atomic energy industry. This will provide an ever-increasing proportion of the world's power resources as fossil fuels become depleted. and it will become essential in the long-term development of Australia. The most promising energy source after fission resources become exhausted—and they will have a life-time of some 50,000 years—is again a nuclear one. It arises through the synthesis of heavier elements from lighter ones through fusion or thermonuclear reactions similar to those we now know provide the major source of stellar energy.

Fission and fusion then are two compelling practical reasons why any forward-looking country must study low-energy nuclear physics.

My final reason is probably the most important. Although we have an ever-increasing knowledge of the properties of nuclei, we are still far from understanding the detailed structure of nuclei, and the seat of the very strong nuclear forces which bind the nucleons together in a nucleus. It is a major aim of nuclear physics research to try to provide such understanding.

To illustrate the scale on which one needs to operate in low-energy nuclear physics these days, I can do no better than to describe our new installation in Canberra. The ingredients for nuclear experimentation are: (1) appropriately prepared targets; (2) an accelerating machine with which to produce the fast particles with which to bombard the target; (3) detecting and recording equipment to observe the particles or radiation leaving the target as a result of nuclear reactions.

Target preparation is an art in itself, and will not be discussed here, but I should say something about the other two since this is where the big expenditure and effort lie.

To-day, for precision work in nuclear physics, the choice of the experimentalist is for an electrostatic accelerator of the type first built by R. J. Van de Graaff in the United States. Such machines are exceptionally useful for investigating properties of nuclei because they produce highly collimated beams of bombarding particles the energy of which can be varied continuously and smoothly, and they yield particles which are nearly monochromatic in energy.

The operating principle of a conventional electrostatic generator is illustrated in Fig. 1. An endless belt, *B*, of rubberized fabric, runs over two pulleys placed one above the other. Electric charge from a power supply, *G*, is sprayed on to the lower end of the rising half of the belt by means of corona discharge from points on a metal comb, *C*. The charge is carried up by the belt and at the top enters a spherical hollow metal terminal, *T*, to which the charge is transferred from the belt by means of another comb, *C′*. Alternatively, charge of the opposite sign can be sprayed on to the belt from another power supply, *G′*, inside the terminal. In this way, the positive charge on the terminal is continually built up, the potential obtained being limited only by the rate at which it leaks off, or by electrical breakdown to the surroundings.

An evacuated acceleration tube, consisting of alternate sections of glass and metal, connects between the terminal and earth potential. An ion source mounted at the upper end of this tube supplies positively charged particles such as protons, deuterons or tritons, and these are accelerated through the potential difference between the terminal and the ground. The higher the maximum voltage to which the terminal is required to be raised, the longer the accelerator tube needs to be and the larger the diameter (and therefore the electrical capacity) of the terminal must be to withstand the voltage stress.

In actual fact it turns out that 6–7 million volts is the practical limit, partly because, beyond this figure, the total stored energy in the terminal ($\frac{1}{2}$ CV^2) is so great that any odd arc discharge from it to the surroundings causes great damage to the system. Unfortunately, 6 million volts are insufficient for many of the problems we want to attack, and it became necessary to improve on this. The machine just completed at the Australian National University will allow particles to be accelerated to more than 12 MeV. and is a tandem accelerator. It employs ion exchange techniques for increasing beam energy which were suggested many years ago by W. H. Bennett, but which at the time were not practical. Renewed interest in the idea occurred when physicists learned how to produce negatively charged hydrogen ions, that is, protons to which two electrons have been attached. Such ions can be produced with an intensity of about 2 parts in 100 when a beam of protons, accelerated through a potential difference of about 20 kV., is allowed to pass through hydrogen gas. Under such conditions the velocity of the protons corresponds approximately to the velocities of the outer orbital electrons in the gas atoms and leads to the formation of the negative ions. This negative ion beam is then analysed magnetically so that unwanted particles, such as neutral particles and electrons, are removed from the ion beam. The clean ion beam is then injected into the tandem accelerator, as indicated in Fig. 2. The negative ions are accelerated by the positive voltage on the central high-voltage electrode of the machine. When they reach this terminal the negative ions are moving with a centre of mass velocity which is large compared with that of the outer electrons about a nucleus. In these circumstances, by allowing the ion beam to pass through a tube containing gas (called the 'stripper' tube), electrons are stripped off and the emergent beam consists of positively charged particles. The gas pressure in the stripping canal can be maintained at a low enough value so that the energy lost in passing through the gas is negligible (less than 0·5 keV.). The positive ions so formed are then pushed away from the positively charged central terminal and are accelerated in the second half of the stack. The energy of the emergent beam is therefore twice that of the terminal voltage and, with 6 MV. on the terminal, the emergent beam has an energy of 12 MeV.

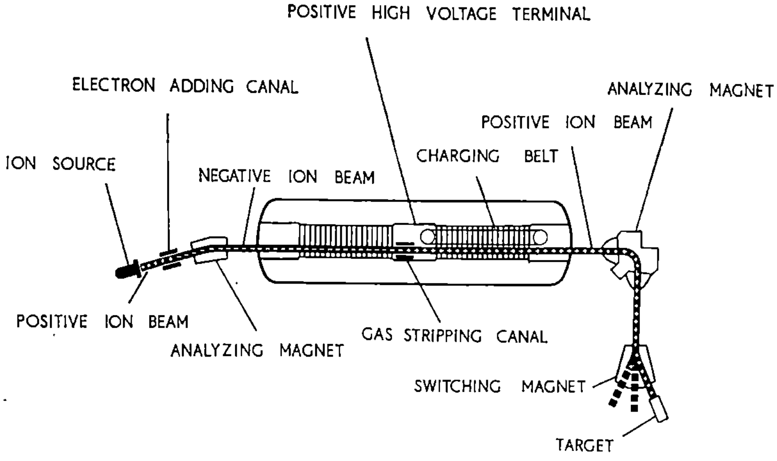

Fig. 2. Functional diagram of the operating principles of a tandem electrostatic accelerator

The tandem generator has many possibilities for experimental work. It is the most flexible accelerating machine yet built, for the reason that the ion source and the target assembly are both at earth potential and readily accessible to the experimenter (the ion source in the conventional Van de Graaff generator, Fig. 1, is in the high-voltage terminal within the pressure shell of the machine and is inaccessible).

Proton and deuteron beams with energies of about 12 million volts and oxygen ions with energies of 30–40 MeV. can be readily obtained. In the more distant future, ion beams of lithium, fluorine, and any other element capable of forming negative ions (a criterion which includes about half the Periodic Table) may be produced.

Unfortunately two very important projectiles, helium-4 and helium-3, do not form negative ions long-lived enough to be accelerated with intensity comparable with protons, deuterons or tritons. In the near future, therefore, we are planning to install an injector which will make such acceleration possible. This will use a conventional 2 million volt electrostatic machine in which He$^+$ ions are accelerated to about 700 keV. (which is an optimum figure for the purpose), neutralized in a charge-exchange canal, injected into the tandem machine and allowed to coast, without gaining energy, to the high-voltage terminal. There, as before, they are stripped of two electrons, becoming He^{++}, and in falling through the potential difference of 6 MV. in the second accelerator tube gain 12 MeV. of energy to emerge with a total of 12·75 MeV. The injection machine will be mounted on a turn-table and railway arranged so that, when not in use for helium-ion injection to the tandem, it can be run back into an adjacent laboratory, rotated through 140° and used as a 2-MeV. accelerator in its own right in conjunction with an appropriate analysing magnet which can switch the beam into either of two directions for experimental work.

This example of the helium-ion injector illustrates one of the great advantages of the tandem accelerator. Because the ion source is at ground potential and readily accessible, there are virtually no limits to the power consumption, size and complexity of the injector system. For example, mμsec. time of flight techniques (which are important in many experiments) can be applied very readily with the tandem generator, since radio-frequency deflexion and bunching can be carried out on the low-energy beam before injection. Further, it may be possible in the future to polarize the nuclei of negative ions and eventually produce beams of polarized ions, which would open up entirely new fields of experimentation.

Preliminary experiments with the tandem accelerator show that the peak-to-peak ripple at 5·1 MV. on the high-voltage terminal under beam conditions is 1·6 kV. with a slow drift of 0·5 kV. The voltage stability of the beam is therefore better than one part in a thousand, and to make use of this it is necessary that precision detecting equipment be available in the target area.

Two major units will be available for precision experiments—a 24-in. double focusing 180° spectrometer and a 65-cm. Buechner particle spectrograph, both of which can analyse the charged particles leaving a target under bombardment. The former incorporates a 20-ton magnet having a specially shaped magnetic field of value quadratically dependent on the radius of the particle trajectory in it. In cylindrical polar co-ordinates there arises a radial component of the field in addition to the z-component, enabling focusing in the z-direction to be effected as well as radial focusing. By shaping the field so that the coefficient, α, of the first-order term of $H_z(r)$ is exactly one half, the radial and z-focuses coincide for all values of object distance, and in our spectrometer object distances 9–26 in. from the field boundary can be chosen. The size of the image given by such a magnet depends on the object size and aberrations. Aberrations can be reduced considerably by choosing the coefficient, β, of the quadratic term in $H_z(r)$ correctly. The pole-face profile is therefore complicated, but successful achievement leads to a greater solid angle of particle acceptance. In the present instrument, for equal object and image distances the solid angle of acceptance is 0·01 steradian at 0·1 per cent energy resolution for fields up to

THE COMMONWEALTH LIBRARY
OF SCIENCE, TECHNOLOGY AND ENGINEERING

Chairman of the Honorary Editorial Advisory Board:
Sir Robert Robinson O.M., F.R.S.

The first volume of a 1,000 *volume original paperback series in aid of education*

ON TEACHING MATHEMATICS

A report on some present-day problems in the teaching of mathematics, being the outcome of discussions and lectures at the **Southampton Mathematical Conference, April 1961,** *under the Chairmanship of*

Bryan Thwaites

Can Britain survive in a Technological Age ?

Ultimately it all depends on education, and upon school mathematics in particular. Today British schools are desperately short of mathematics teachers, of whom British universities are not producing enough. The weakening foundations of our educational structure are swaying beneath the ever-increasing load of science and technology. Even the best and fastest rescue operation will take a decade to right it all. Questions in the House of Lords, in the Commons, and letters in *The Times* have foretokened the anxious years ahead.

What are our chances of remaining a first-class industrial power ? How bad are things ? What must be done ? ON TEACHING MATHEMATICS contains the findings and recommendations produced in answer to these questions by professional mathematicians drawn from schools, universities and industry at the 10-day Southampton Conference.

It is most appropriate that the first volume to be issued in this Library should be this important book on the teaching of mathematics, which will undoubtedly have a profound effect on and be a great help to everyone who teaches mathematics or is interested in the wider field of education.

The Pergamon Press leads amongst the international scientific publishing houses, and is proud to play its part in current affairs of great moment.

This valuable paperback is available from all booksellers, or in case of difficulty direct from the Publisher, price 7/6 net ($1.25).

GD604

What's he up to?

He's weighing to an accuracy of 1 MICROGRAM!

He's doing it on the filing cabinet just to show you—he could do it on anything else just as easily. He's not worried about levelling, draughts, temperature or vibration.

And he's not worried about his results; he knows that with the CAHN ELECTROBALANCE he has an accuracy of 0.05% and a reproducibility of 0.02% on each of the instrument's six scale ranges—0–1mg to 0–100mg—and with no 'ifs' or 'buts.'

This weighing will take him less than one minute. Then he'll hand the balance back to the colleague he borrowed it from—with one hand: it weighs only 12 pounds. And he knows it will give just the same first-class performance next time he borrows it—because he can calibrate it in a matter of a few seconds every time he sets up to weigh.

He's a happy man. And so is his Director. Because this *one* versatile, portable CAHN ELECTROBALANCE replaced *four* conventional micro-balances—and does the same work, MORE ACCURATELY, MORE EASILY and FASTER.

Two other versions of the Cahn Electrobalance are available. One has the capacity to weigh small samples up to 1gm much more easily, quickly and accurately. The other is an automatic version of the balance featured above.

THE CAHN ELECTROBALANCE

is a revolution in micro-weighing

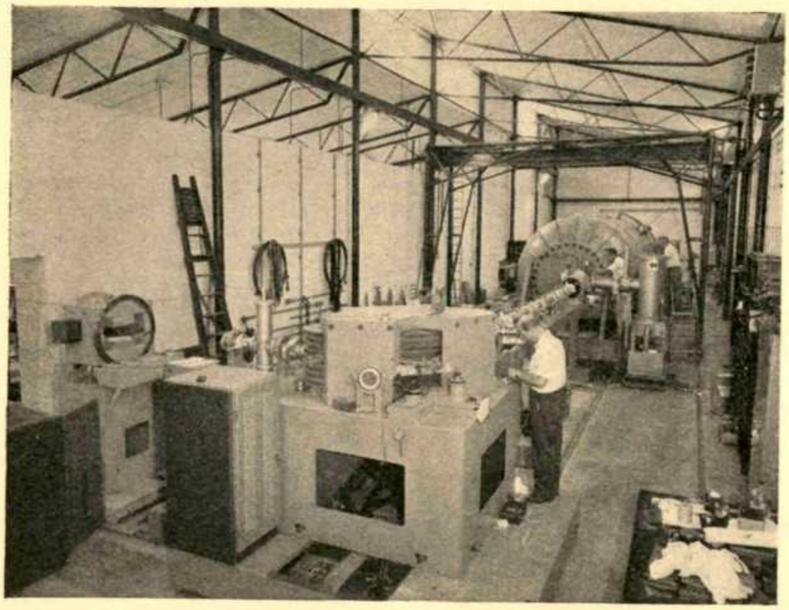

Fig. 3. The tandem accelerator at the Australian National University viewed from the high-energy end. In the foreground is the 90° analysing magnet. On the left (not yet connected to the machine) is the switching magnet which allows three beams, + 25°, 0 and − 25°, to be obtained. The accelerator pressure vessel is in the background

10,000 gauss—sufficient to analyse protons of energy up to some 25 MeV. In use it is mounted on a trolley and is fed with current through flexible cables so that it can be rotated around a target from + 10 to − 155° to analyse reaction products as a function of angle.

The second major piece of equipment—the Buechner spectrograph—will be installed early in 1962. It differs from the spectrometer in that it will accept and analyse particles having a wide range of energies simultaneously; in fact, at one field setting particles in the energy-range from E to $2{\cdot}4\,E$ are recorded. In this case the magnet employs a uniform field having a circular boundary which focuses particles from the target located outside the field along a hyperbolic focal surface also outside the field after a mean deflexion of 90°. Again an energy resolution better than 1 part in 1,000 can be achieved and recording is by nuclear emulsion, the plate being bent to take up the shape of the focal surface. With this device the solid angle of acceptance is much smaller—about $1{\cdot}4 \times 10^{-3}$ steradian—but the photographic emulsion detector can integrate the particle spectrum over a lengthy run and over the wide range of energies. At a field of 12,000 gauss the spectrograph will record protons and α-particles up to 35 MeV. and deuterons up to 17-MeV. energy. The magnet weighs 16 tons and can be rotated about the incident beam from −10° to +130° to enable angular distributions to be measured.

In addition to the spectrometer and spectrographic methods of analysing reaction products, the more conventional electronic—gas counter, scintillation counter—and nuclear emulsion techniques will be employed.

The more recently developed silicon surface barrier detectors are likely to have very wide application; they are compact, with a 100 per cent detection efficiency for charged particles, a linear energy-dependence over a wide range and extremely short pulse rise time. In some of those we have made in the laboratory, energy resolutions of 1 per cent have been achieved for α-particles and this necessitates the use of low-noise amplifiers. Unfortunately, at present, the layers are thin for protons and detect linearly only up to some 3 or 4 MeV. These counters, however, are ideal for many purposes—particularly the simultaneous study of particles emitted at a number of angles from a target.

Most detectors present a problem of pulse-height analysis—determination of the spectrum of pulses arising from them and multichannel kicksorters capable of accepting the data, sorting it into 400 or 512 channels, storing it for the duration of a counting period and then printing it at the end of the run are necessary. For reliability these devices are largely transistor operated; we have two in operation and will install another two in the course of the next year.

The foregoing review will indicate that in the immediate future experimental nuclear physics is well cared for in the Melbourne and Canberra laboratories, while theoretical nuclear physics is flourishing both in these laboratories and in other universities too (Table 1). The question may be asked whether there should be more work in the general field. This must be answered in relation to the problem of a balanced development of physics in the country. To set up a new and effective Department of Experimental Nuclear Physics would require a capital investment of between half a million and one million pounds, with running expenses of perhaps £150,000 per annum. However enthusiastic one may be about the discipline, it must be admitted that in the present stage of national development, such funds put into other, possibly less-glamorous and less-spectacular but no less-important, parts of the physical sciences, would ensure a better balance in the overall development of physics in Australia. But we, like other Western countries, will have to build further universities in the next two decades and it may be that expansion of nuclear activities could take place then.

Along with some others of my colleagues, I have become concerned at the way research in physics is being represented to the public. In the public mind there is a tendency to believe that the building of nuclear reactors, the placing of satellites into orbit, the production of nuclear bombs and the plans for men to visit the Moon are science. Such projects do, of course, use the knowledge gained in past research, but at best they are applied science, and more generally steps in a development programme; as such, of themselves, they add little to our store of fundamental knowledge.

Pure research in physics cannot be carried out in the full glare of publicity of Press, radio and television. There is nothing certain about it; it flourishes quietly and methodically in the laboratory. Its results go to acknowledged responsible scientific journals both in Australia and overseas, and its merit is judged by colleagues in the international community of scientists.

THE ROAD RESEARCH LABORATORY

OPEN days were held by the Road Research Laboratory (Department of Scientific and Industrial Research) on Wednesday and Thursday, May 3–4, 1961.

The work of the Traffic and Safety Division was shown at the new Road Research Track at Crowthorne, Berkshire. The track is three miles long and is in the form of a figure eight with a large paved area 900 ft. in diameter in the centre. A detailed description of the track has been given in *Nature* (188, 894; 1960).

The display at Crowthorne comprised static exhibits in marquees and in an underground laboratory, and several demonstrations of the work on vehicles, skidding, road user behaviour, and traffic.

In one marquee, equipment used in traffic studies was on view and included traffic counters, a recording speedmeter, data recorders and multi-channel telemetry equipment for traffic studies over wide areas.

Traffic and Safety

Demonstrations were given of some of the work undertaken in the application of electronic guidance to motor-vehicles.

A car was driven along a bend on part of the track in which detector loops were buried in the road. The passage of the car caused lights to be switched on, and remain on until the car was three loops away. In fog such a device could reveal to a driver in a car how far ahead the road was clear. Similar detectors could be used to check the speed of passing vehicles and warn drivers when they were exceeding the speed limit.

In another demonstration of the use of electronic control, a car with its windscreen blacked out was driven along a straight section of the track. The driver was guided by his instruments, which were actuated by two coils at the front of the vehicle to pick up impulses from a guide wire on the ground. An audible signal was transmitted to the car, and for the purpose of demonstration was amplified over a loudspeaker system. When the driver was on course the signal was heard loud and clear, when the driver moved away from his predetermined course the signal was weak. The transmission is actually made from the roadside via the guide wire beneath the centre of the track. On a road equipped with a guide wire this system could be used by traffic police to communicate with a motorist who had a suitably modified radio installed in his car.

A possible development from these investigations, which are at present in their early stages, would be to link the signals direct to the controls of the car and thus drive the car automatically. In fact, in some runs the car steered itself entirely by electronics and was kept within 6 in. of the guiding cable.

The greater resistance to skidding, and the shorter braking distances, that can be achieved with tyres having tread rubber with a high hysteresis loss was demonstrated by two identical cars, one following the other and about 30 ft. apart, at a speed of about 40 miles per hour on a wet, slippery section of the track. At a given signal, each driver applied his brakes as in an emergency stop; the car equipped with conventional tyres travelled farther in coming to rest than the one fitted with tyres with tread rubber with a high hysteresis loss. Experiments have shown that by this means braking distance can be reduced by about 14 per cent.

Another series of demonstrations showed the advantage of fitting devices which prevent wheels from locking when brakes are applied. A car was driven at 45 miles per hour on a wet surface, and the driver applied his brakes as hard as possible to lock the wheels. When using Maxaret units to prevent wheel locking the driver did not lose directional stability and was able to retain steering control and bring the car to a stop in a much shorter distance.

To help analyse the cause of accidents the Laboratory is using a camera suspended on a 40-ft. collapsible pole which protrudes from the roof of a van. The camera photographs, from above, the exact position of vehicles that have been involved in an accident. By this means it is hoped to obtain information on deficiencies in vehicle design and road layout.

The Laboratory has been co-operating with the glass industry in attempts to improve vision through toughened glass windscreens when they shatter. By reducing the fragmentation of the glass to between five and ten particles per inch in the part of the windscreen immediately in front of the driver he is given reasonable vision when the glass is shattered. The effectiveness of the new glass was demonstrated by driving a car with a shattered windscreen and manœuvring it around obstacles at about 20 miles per hour.

The problem of getting information across to road users in the most efficient way was shown by a demonstration in the central area. Signs were mounted on a car which was driven towards the spectators, who were then invited to record by pressing push-buttons when they could read the signs; the distances at which they could do this were clearly indicated. Signs with different types of lettering were used.

About a hundred people are killed each year on the roads in Britain as a result of cars striking lighting columns. The Laboratory is examining the design and positioning of columns with the view of minimizing injuries to road users. A film showed the effect of an 8 h.p. car hitting four types of lighting column—concrete, tubular and thin sheet steel, and aluminium.

The vehicle detectors now in use on the road can register moving vehicles only; they cannot therefore distinguish between dense stationary traffic and the complete absence of vehicles. Two devices that can detect the presence of moving and stationary vehicles are now under development; both depend on the change in the magnetic field produced by a nearby metal object.

The Laboratory has been examining the possible applications of vehicle-presence detectors and a demonstration was given of the detection of congestion in a roundabout. The equipment was also used to indicate imminent 'locking up' at a signal-controlled roundabout.

A prototype device was shown that is being used in experiments with vehicle-actuated traffic signs on high-speed roads. As shown in a series of demonstrations, it ensures that the traffic signals will not change from green to amber when a driver approaches an intersection at such a speed that he can neither stop safely nor clear the intersection before the 'red' appears. A transistorized form of the device is now under development by manufacturers.

Materials and Methods of Construction

The work of the Materials and Construction Division was shown at Harmondsworth, Middlesex, where research is undertaken on pavement design, soil moisture and surface drainage, bituminous materials, concrete and special problems such as those arising from snow and ice and the measurement of surface irregularity. The Laboratory's Tropical Section is also at Harmondsworth.

A number of exhibits dealt with the problem of designing road pavements in relation to foundation conditions and the traffic to be carried. The Laboratory has many full-scale road experiments in progress in which the performance of short sections laid on heavily trafficked routes is being studied. The main variables are the thickness and type of both surfacing and base in the case of flexible roads and the thickness of slab and weight of reinforcement for concrete roads. Results from experiments which have been in progress for periods up to twelve years were shown.

Severe frost, which occurs on average every 10 years, can cause damage to road foundations. In a refrigerated road full-scale freezing tests on a typical road section were in progress. Apparatus was also on view for studying the moisture retention and swelling of soils, and photographs showed the relation of this work to practical problems associated with pavement failures.

The function of a road pavement is to spread the wheel-loads so that the stresses in the soil and other layers of the road structure do not cause unacceptable permanent deformation. This load-spreading depends on the elastic properties and thickness of layers in the road. The stresses in the structure and in the soil can be determined theoretically and they are also being measured by equipment developed at the Laboratory. Exhibits were concerned with dynamic stresses measured under different forms of flexible construction and with the effect of repeated applications of these stresses.

In one building were assembled rainfall recorders and flow-measuring apparatus devised at the Laboratory for use in research on surface-water drainage. The main objective of this work is the design of drainage systems both in relation to their efficiency and their cost. Apparatus is being devised for printing hydrological data directly on to tape for analysis by an electronic digital computer. A working model was shown of a novel automatic recording salt-velocity apparatus devised jointly by the Road Research Laboratory and the Hydraulics Research Station. The apparatus comprises a device for injecting charges of salt solution into the sewage (each charge is triggered at a pre-set depth of flow by a water-level recorder), two pairs of electrodes in the sewer and apparatus for recording the change in conductivity as the salt charges pass the electrode. This enables the velocity of flow between the electrodes to be measured for a range of depths; a relation between the rate of flow and the depth of flow is then deduced. Also on display was an analysis of records of rainfall and run-off for twelve catchment areas, employing the rational (Lloyd-Davies) method, the unit-hydrograph method and the Road Research Laboratory hydrograph method. Two methods of calculating sewer sizes for design purposes were on show; both methods were devised at the Laboratory from the results of research into rainfall and run-off. In one method use is made of an electronic computer.

Bituminous binders are viscous liquids adhering to the surface of roadstone. Viscosity and adhesion are therefore two primary properties, and an exhibit described problems connected with the measurement of viscosity, the effects of water on adhesion, and the use, in wet weather, of adhesion agents to prevent damage to a surfacing. The resistance of the binder to hardening under the action of weather plays a major part in road performance; research on hardening was described.

There is at present considerable interest in the possibility of using bituminous materials in the construction of road bases. These materials combine the advantages of a bound material with a large measure of flexibility. Investigations are in progress in the Laboratory on the mixtures to be used, and experimental sections have been included in the full-scale experiments already discussed. The specifications at present recommended were shown.

On rolled asphalt wearing courses in which the stone content is 45 per cent or less, it is normal practice to lay a final application of coated chippings. To spread the chippings uniformly by hand requires skilled labour and slows up the work even where there is no shortage of skilled manual workers. A working model was shown of a machine now under development that spreads coated chippings at a predetermined rate. The machine consists of a hopper and rotating metering device carried on rollers which travel on the surface of the newly laid rolled asphalt. In the construction of new roads the spreader would be carried on rubber-tyred wheels on the concrete edge strip or on the base-course outside the mat being laid.

A group of exhibits illustrated the factors that affect the riding quality of a concrete road and the procedures needed to obtain good riding quality. Experiments undertaken by the Laboratory have shown that, when efficient spreading and compacting machines are used, the riding quality obtained is of a very high standard, the average irregularity index being 32 in. per mile with only 25 per cent of the values greater than 40 in. per mile. No significant differences in riding quality were obtained when different mixes were used, and different mix proportions did not appear to be important when modern power-propelled plant was used.

One of the problems investigated by the Laboratory is the possibility of using prestressed concrete for roads. Tests have been undertaken to determine the performance of thin sections of prestressed concrete. An exhibit showed the comparative costs of reinforced and prestressed concrete roads, work done in collaboration with the Belgian Centre de Recherches Routières, loading tests and measurement of subgrade restraint, and the development of a jack for prestressing slabs by cables with minimum interference with construction. In co-operation with the Belgian research organization a prestressed concrete road was built at Zwartburg, Belgium, in 1960. The experimental road is more than two miles long and includes prestressed, plain and reinforced concrete slabs. The performance of the road under traffic is being observed, and the possibility of carrying out loading tests will be considered at some future stage.

In recent years sections of road have been constructed with heating wires placed in the upper layer of the road structure to prevent the formation of ice and frost, and to melt snow. A control device automatically switches on the heat when the road surface is cold and wet. The control device was shown in operation. The heating system has been installed in the underpass at Hook on the Kingston by-pass road (*A*.3) and in the one nearing completion at Hangar Lane, Ealing (*A*.40), on a bridge at Basildon, Essex, and on roads in Edinburgh, Slough and Harmondsworth. The Laboratory has also assisted with the design of the heating systems for many sections of road, including the Hammersmith fly-over, the Hyde Park Corner under-pass in London and for the approach ramps to the new Clyde tunnel in Glasgow.

Tropical Section

One of the main aims of the Tropical Section is to systematize knowledge of the engineering properties and occurrence of the soils and roadmaking materials in different territories. Exhibits illustrated: the nature and engineering properties of soils in individual territories and areas, including the use of aerial photography in terrain evaluation; work on tropical gravels, their use in road building and their suitability for stabilization with Portland cement and hydrated lime; stabilization of sands—full-scale experiment in Nigeria employing bitumen and Portland cement; tests on tropical aggregates; the relation between climate and moisture conditions under roads and runways; pavement design in the tropics.

The rapid growth of road traffic in developing countries is both a factor in the development and a symptom of it. Examples were shown of investigations in Uganda and North Borneo to determine the effects of providing roads on the rate and character of agricultural development. In the expanding towns and cities overseas there are already severe traffic problems and there is at the same time opportunity to plan the future growth of the towns so that the facilities required by future traffic are integrated with the needs of the community as a whole. Examples were shown of investigations undertaken in Hong Kong, Kingston (Jamaica) and Lagos to ease present traffic problems and to plan future needs.

Scottish Branch

The Scottish Branch of the Laboratory held open days during June 7–8 at Thorntonhall, Glasgow. The Branch was established in 1949 with the view of investigating problems of particular interest to Scotland, making known to all concerned with roads and traffic in Scotland the results of work undertaken at the parent Laboratory in England, and encouraging the application of the results of research.

While many of the exhibits displayed at Thorntonhall were those originally on view at Crowthorne and Harmondsworth, there were a number that illustrated the work undertaken in Scotland.

An investigation is being carried out on the effect of the new Forth road-bridge on the traffic patterns in the region. An exhibit described with photographs and maps an origin-and-destination survey carried out during the whole of one week in August 1960. Vehicles were stopped at three survey stations and more than 8,200 drivers, or about 43 per cent of the total, were questioned to obtain information on the traffic in the region before the opening of the new bridge. Analysis of the information obtained has not been completed, but preliminary results show that 22 per cent of the journeys start and terminate in Glasgow or Edinburgh, and about 34 per cent in five major cities.

The effect of new towns on the generation of traffic and on traffic patterns is being studied using East Kilbride as a 'guinea pig'. Such studies should assist planners in predicting facilities required for new towns, for example, the number of lock-up garages that should be provided. In East Kilbride there is one car for every three families.

There is a shortage of crushed stone in certain parts of Scotland, and the Laboratory has been examining the possibility of using morainic (glacial) gravels for the construction of road bases and surfacings. For the base, glacial gravels are mixed with cement to produce a 'lean concrete', for surfacings they are mixed with bitumen to provide a reasonably cheap and durable wearing course. Since 1956 many short sections of road containing glacial gravels—each with a different composition—have been laid in various parts of Scotland. The results so far are very promising.

Peat occurs in many regions in Scotland. This soft, water-filled, organic material is compressed when a road is constructed on it and this often results in an uneven road surface with a poor riding quality. A group of exhibits showed how the Laboratory is tackling the problem of building roads on peat.

OBITUARIES

Prof. A. W. P. Wolters

PROF. A. W. P. WOLTERS, who died recently, was the first holder of the chair of psychology in the University of Reading and played an outstanding part in dissolving academic distrust of his subject and achieving its recognition. His patience in handling the problems of its acceptance in the outside world was effective as well as exemplary. As deputy president, during 1936–38, and as president, during 1939–41, of the British Psychological Society, he took a leading part in the difficult transformation of a somewhat ungainly association into an incorporated body with specific professional, as well as scientific, aims. Wolters, too, was among the first to urge the opportunity and the need to employ people with a psychological training in the event of war. Unusual hardihood and a complete lack of aggressiveness enabled him to survive the official flood of waste-paper and committee proceedings which resulted. The idea that objective study of the human organism is not irrelevant to human welfare and efficiency thus gained some degree of official recognition in war and survived to spread effectively in peace.

Wolters learnt his psychology, both academic and practical, the hard way. As a fourteen-year-old pupil-teacher, he had charge of the mental defectives "who littered the enormous classes" of the Board School where he taught. Perhaps this experience stood him in good stead later on. His catholic intelligence responded to such education as came the way of a pupil-teacher, and in due course he entered University College, Reading, where he was to live and work for almost the rest of his life. W. L. de Burgh, the professor of philosophy, gave him such scope as was available to introduce psychology, and the good judgment with which Wolters handled this admirable but hazardous opportunity ensured a much earlier start for an independent department and honours school at Reading than was possible in many other places. His quiet advocacy, too, prevailed among manifold claims and restricted resources and somehow saw to it that a specially designed laboratory was built. Here, in the years which followed the War, he built up a school of psychology modest in size, but the quality of which aroused the envy and admiration of his colleagues elsewhere. At the same time his self-effacing talents were devoted to his University—he became deputy vice-chancellor in 1947—then preparing for complete removal to Whiteknight's Park, and beset by the difficulties of post-War expansion. His moderation and his constructiveness in meeting these problems were indispensable.

Wolters's modesty and simplicity were inherent and free of contrivance, his perceptiveness unforced. His qualities stirred young people much, but himself only a little, to intellectual achievement. His main explicit contribution to psychology—an extension of Head's concept of *Schema* into the field of conceptual thinking—is an original contribution the full implications of which probably remain to be appreciated. But the inspiration of his teaching and the gentleness with which he deflated the pretentious will long be remembered and admired. R. C. OLDFIELD

Prof. A. F. Kapustinsky

ANATOLY FEDOROVICH KAPUSTINSKY was born in Zhitomir on December 19, 1906, and died in Moscow on August 26, 1960. He studied chemistry in the University of Moscow, from which he graduated in 1929. His main field of research was in physical chemistry and thermodynamics. He was particularly interested in work on the energetics of chemical reactions, in the energy of the crystal lattice, in crystallochemistry and its application to geology. In 1933 he proposed the second principle of crystallo chemistry, namely, that the energy of the crystal with its attendant properties is determined by the number of ions, their radii, their valencies, and their degree of polarization. At the same time he proposed a simplified equation for the energy of the crystal lattice in ionic crystals, and in 1943 he produced a revised equation, which enabled him to calculate the energy of the crystal lattice of compounds with complex ions. Still later, he produced a number of equations applicable to various crystallochemical problems.

Besides these problems, Kapustinsky tried to solve many others, especially in thermodynamics. In collaboration with B. A. Shmelev, he devised a new method of physico-chemical analysis which enabled them to study complex equilibrium systems. He also published numerous papers dealing with thermochemical methods, with ionic compounds, electrolytes and chemical technology. By introducing the zero period into the Periodic Table he developed the idea of secondary periodicity which he linked with the periodic structure of atomic nuclei. This led him to discuss matter subjected to high pressure and then to apply these ideas to his new "Theory of the Earth" (see *Nature*, 180, 1245; 1957).

During his busy life, Kapustinsky occupied the following posts: professor of physical chemistry at the University of Gorky (1933–37); the same post at the Moscow Steel Institute (1937–41) and also at the University of Kazan (1941–43); professor of general and inorganic chemistry at the Chemical-Technological Institute in Moscow (1943–60). In 1939 he was elected corresponding member of the Academy of Sciences of the U.S.S.R.

Kapustinsky's publications are varied and numerous. Besides pure research, he published some thirty papers dealing with topics related to the history of chemistry. He also edited many books translated into Russian.

In private life Kapustinsky was a most jovial fellow and a very versatile conversationalist, and his death at the early age of fifty-four was deeply felt by his friends, of whom he had many.

S. I. TOMKEIEFF

NEWS and VIEWS

Applied Mathematics at Manchester : Dr. F. Ursell

THE Beyer professorship of applied mathematics at the University of Manchester is to be filled by Dr. F. Ursell from October 1, following the departure of Prof. M. J. Lighthill for the Royal Aircraft Establishment in 1959. Dr. Ursell is at present a lecturer in the Department of Applied Mathematics and Theoretical Physics, University of Cambridge. He took the Mathematics Tripos at Cambridge during the early years of the War (in company with his predecessor in the Beyer professorship), and spent the remainder of the War at the Admiralty Research Laboratory, Teddington. The introduction which he gained there to problems associated with water waves evidently made a deep impression, for he has pursued such problems steadily and successfully since that time, and has done much to revive interest in a 'classical' subject which—like so many others—was thought to be well understood and well tilled until war needs revealed deficiencies. In 1947, he was elected to a research fellowship at Trinity College, Cambridge, for a dissertation embodying his research on water waves. A short time later, he proceeded to the University of Manchester, where he held an I.C.I. Fellowship, returning to Cambridge to take up a lectureship in 1951. He was eventually elected to a research fellowship at King's College, and has received other tributes to his research, which is characterized by great analytical power. He is interested in a wide variety of mathematical techniques, and can be expected to maintain the high reputation of Manchester as a centre of teaching in applied mathematics.

Electrical Engineering at Birmingham : Prof. J. T. Allanson

MR. J. T. ALLANSON has been appointed to the recently established second chair in the Electrical Engineering Department in the University of Birmingham. In this post he will be responsible primarily for the undergraduate work of the Department. Prof. Allanson entered the Department of Electrotechnics in the University of Manchester in 1938, taking his B.Sc. in 1942 and his M.Sc. in 1944. Although he had worked at the University on waveguides, he took for a year a post with Callenders Cables, Ltd., concerned with power cables and the cross-channel petrol pipe-line, and then went to Ultra Electric, Ltd., for two years to work on general electronics, including radio receivers. In 1947 he was appointed head of the Electrical Laboratory at the Telegraph Construction and Maintenance Co., Ltd., and was concerned once more with cables. In 1949 he was appointed lecturer in electrical engineering in the University of Birmingham, becoming senior lecturer in 1957. He is a man of very wide interests, embracing philosophy and biology as well as engineering; and, indeed, his strongest research interests lie in the field of nervous systems and particularly the mechanisms of hearing, and he has made some original contributions to this in co-operation with colleagues in the Department of Physiology. He has a strong natural interest in electrical net-work theory, and has published a number of papers on this topic, being particularly concerned with net-work synthesis. But his strongest enthusiasm is probably for teaching and students, and he has experimented in a number of ways to find better methods of teaching and to improve staff–student understanding and co-operation. He is also very interested in university administration. His appointment will give much satisfaction to his colleagues.

The Royal Scottish Museum, Edinburgh :
Dr. Douglas A. Allan, C.B.E.

On September 15, Dr. Douglas A. Allan retires from the directorship of the Royal Scottish Museum, Edinburgh, the destinies of which he has controlled for nearly seventeen years. After graduating at Edinburgh he became assistant to the professor of geology in Edinburgh and afterwards was appointed lecturer in geology in Armstrong College (now King's College, University of Durham), Newcastle upon Tyne. Work on Lower Carboniferous geology in Fife earned him a Ph.D., and later on Lower Old Red Sandstone tectonics along the Highland Border a D.Sc. In 1929 he was appointed director of Liverpool City Museums. In 1945 he became director of the Royal Scottish Museum, and returned to his native Edinburgh to complete his active professional career. Under him, the Museum has played a much more prominent part both nationally and internationally, for he has served on the Joint Committee of the Carnegie United Kingdom Trust for twenty-five years, advising on the allocation and utilization of development grants, was chairman of the British National Committee of the International Council of Museums (Unesco) for seven years, and this year is president of the editorial board of *Museum* (Unesco). In 1952 he was director of the first Unesco seminar on "Museums and Education", held in New York. Under his directorship, the Royal Scottish Museum has been modernized in display techniques, has rendered wide service to research in many fields, and has embarked on schemes of periodical exhibitions of educational and cultural value. His early exploring adventures are reflected in his four years tenure of the presidency of the Royal Scottish Geographical Society and his official museum tours in North America, Asia and Central Africa.

Mr. Ian Robertson Finlay

Mr. Ian Finlay, who succeeds Dr. D. A. Allan, was born in New Zealand but educated in Edinburgh, graduating M.A. with honours in the history of art. He joined the staff of the Museum in 1932 and was successively assistant keeper and, since 1955, keeper of the Department of Art and Ethnography. He is particularly interested in display methods in all types of museums and will bring his undoubted talents to the front at an important time in the history of the Museum, which has practically completed its major overhaul since the Second World War. Mr. Finlay is secretary of the Royal Fine Arts Commission for Scotland, a Freeman of the City of London and a Member of Livery of the Worshipful Company of Goldsmiths, London. He has a strong interest in contemporary Scottish crafts and is a leading authority on Scottish gold and silver, having written several books and broadcast on numerous occasions. Last year he was awarded a Leadership grant by the United States Government to enable him to visit museums and galleries in North America.

Mr. Cyril Aldred

Mr. Cyril Aldred succeeds Mr. Finlay as keeper of the Department of Art and Ethnography of the Royal Scottish Museum. Born in London, he was educated at Sloan's School and entered later on a course of study in the History of Art at King's College, London, and the Courtauld Institute, graduating as a B.A. in 1936. He was appointed assistant keeper in the Department of Art and Ethnography in the Royal Scottish Museum in June 1937, and has served that Department with distinction ever since, except for one lengthy break with the Royal Air Force during the Second World War, and two years as associate curator in the Egyptian Department in the Metropolitan Museum of Art, New York. From an early stage he has taken a very strong interest in Egyptology and the life and arts of ancient Egypt, a field in which he now has an established reputation, and in which he has published a considerable amount of work, both on the monograph and the popular level. A competent practitioner himself in gold and silver craftwork, he is particularly well qualified to judge standards and methods in the works in his care, and brings a new attitude to the study of the ancient Egyptians to that more commonly brought by the philologists. He has already made a notable impact on museum techniques by his staging of exhibitions, both temporary and permanent, and in the latter, in Edinburgh, introduced the novel idea of employing contemporary writings to explain and illuminate his ancient Egyptian exhibits—rather than the 'hindsight' view of a twentieth-century savant.

Veterinary Anatomy at Liverpool :
Prof. A. S. King

Dr. A. S. King, senior lecturer in veterinary anatomy in the University of Bristol, has been appointed professor of veterinary anatomy in the University of Liverpool. He is thirty-nine years of age, and was educated at Felsted School, Essex, and the Royal Veterinary College, London, where he obtained the degree of B.Sc.(Vet.Sci.) in 1946 and the degree of Ph.D. in 1956. During July 1945–December 1950 he held teaching appointments at the Royal Veterinary College, London. In January 1951 he was appointed lecturer in veterinary anatomy in the University of Bristol, and senior lecturer in veterinary anatomy in 1960. During 1960 he held the post of visiting associate professor in anatomy in the School of Veterinary Medicine, Philadelphia. Dr. King has been a member of the consultant editorial board of *The Journal of Small Animal Practice* since its inception.

National Reference Library of Science and Invention

Aslib Proceedings for July (13, No. 7) includes a report of the discussion meeting on the National Reference Library of Science and Invention arranged in London on May 9, at which Prof. R. S. Hutton had urged the paramount importance of the potential users' requirements in planning the Library, and expressed his doubts as to the adequacy of present plans and intentions. Sir Frank Francis said that the British Museum would have preferred to have the new Library entirely on the Bloomsbury site, but use of the South Bank site would permit full operation by 1965, whereas development of the Bloomsbury site would not be completed until 1985. The National Library of Science and Invention would be one of a number of departmental libraries of the British Museum, the work of which would be thereby co-ordinated. There would be a separate science library in Bloomsbury devoted to the historical material; current material would be held on the South Bank. The new Library would be limited to 500,000 volumes because the appropriate committee of the Advisory Council on Scientific Policy thought this was the largest number compatible with open access. All material discarded from the National Reference Library would go to the British Museum collections. Research was needed on documentation services for scientists and provision had been made for this in the plans. It had been hoped to include rooms for lectures and exhibitions, but, in view of the limited space on the South Bank, these facilities and accommodation for investigations into the use of scientific literature would be provided in Bloomsbury. Investigations were being made to determine the reference services that were needed and the results would be made public. A general reference service would be provided at Bloomsbury. In the discussion the need for a first-class reference and information service was stressed, and also the importance of a rapid shuttle service between Bloomsbury and the South Bank, making full use of the latest possible techniques. Prof. Hutton said that his fears had only been partly dispelled: the fundamental importance of the Library was not grasped by policy makers in or near the Government.

The Role of University Extra-Mural Libraries in Great Britain

In *Library Association Pamphlet* No. 21, E. P. Pritchard reviews the aims, organization and methods of university extra-mural libraries in Great Britain and the results so far achieved (Pp. 32. London: The Library Association, 1961. 5*s*., and 3*s*. 6*d*. to Library Association members). This is a comparatively recent development, and in some areas library services for extra-mural courses have an air of improvization, although in others present needs are well on the way to being met. Mr. Pritchard visualizes, however, a considerable growth during the next fifteen years in this side of university work, largely through an increase in the number of extra-mural students who are graduates or have been in a sixth form. He believes the co-operation of extra-mural libraries, public libraries and the National Central Library, which already exists in several areas, could meet almost any foreseeable needs, provided: (1) that library services and the resources devoted to them receive the same emphasis in extra-mural work as in university internal teaching; (2) that each type of library makes the kind of contribution it is best fitted to make; and (3) that tutors never forget the importance of reading in adult education and lose no opportunity of applying this principle. Mr. Pritchard gives an admirably concise survey of various problems and difficulties encountered in practice and the methods of overcoming them.

Zoological Society of London: Annual Awards

The Zoological Society of London will, from 1962 onwards, make the following annual awards for contributions to zoology. These will be in addition to the Society's Gold, Silver and Bronze Medals which have been in existence since 1847.

The Scientific Medal of the Society, which was instituted in 1938, will be presented to a zoologist, less than forty-five years of age, for distinguished work in zoology. The Prince Philip Prize will be awarded to a pupil of zoology, on the basis of an account of some practical work in the field of animal ecology. This will be open for competition to all pupils of zoology in schools in Great Britain, Northern Ireland, the Channel Isles and the Isle of Man, who are studying for the General Certificate of Education A-level examination or an examination of equivalent standard. The award will be a sculpture in bronze, "Animal Head", by Mr. Henry Moore. The entries will be in the form of an essay of not more than 3,000 words, the first award being made in April 1962. Full details will be sent to schools in September of this year, but the regulations can, in the meantime, be obtained from the Zoological Society (Education Department), Regent's Park, London, N.W.1.

Two further awards for contributions to zoology, also sculptures by Henry Moore, have been made possible through the generosity of Granada Television Network. The Stamford Raffles Award, commemorating the founder of the Zoological Society, will be awarded to an amateur zoologist for contributions to zoology, or to a professional zoologist for contributions which extend beyond his field of specialization. This sculpture, "Animal Form", will first be awarded in April 1962. The Thomas Henry Huxley Award will be presented annually to a postgraduate research student in a university in Great Britain and Northern Ireland, for outstanding original work in zoology submitted as a doctor's thesis. This award will also be a sculpture, "Bird", the first award being made in April 1962. Mr. Henry Moore has generously agreed that a limited edition of each of the sculptures may be made, thus establishing the awards for some years. Thereafter the form of award will be reviewed.

Employment of Graduates: a Durham University Survey

The fifteenth annual report of the Durham University Appointments Board, and the third to be published, expresses the view that the demand for graduates of all kinds, from many different types of employers, is still rising, and, generally speaking, more Durham graduates and postgraduate students were seeking first appointments in 1960 than ever before (Fifteenth Annual Réport. Pp. 9. Durham:

Durham University Appointments Board, 1961). Fewer men seemed to be applying to the Atomic Energy Authority, but the Board did not notice the diminished interest in the heavy electrical plant industry found elsewhere. Of male graduates in science taking up paid employment, 13 per cent went straight into school teaching, compared with 12 per cent in 1959; for women, the corresponding figures were 67 per cent and 58 per cent; 50 per cent of the men graduating in arts and 70 per cent of the women went into teaching, and of these, 75 per cent attended teacher training courses. Comment is made on the very low present-day demand for geologists, the acute shortage of mathematicians (the proportion entering teaching has in consequence declined), the increased demand for arts men from industry and the increased recruitment to the public service, though public service overseas attracted only one recruit. The serious lack of information bearing on the proper employment of the woman arts graduate is stressed.

Vision Research

THE appearance of yet another scientific journal is not necessarily a cause for rejoicing, but Pergamon Press is certainly to be congratulated on its initiative in founding *Vision Research*, an international journal the first number of which appeared in June (1, Nos. 1/2; June 1961. Pp. iv + 201. Annual subscription rates: (*A*) for libraries, government establishments, research laboratories, etc., £10 (30 dollars); (*B*) for individuals who place their orders directly with the publisher and certify that the journal is for their personal use, 70*s*. (10 dollars). London and New York: Pergamon Press, 1961). Several different disciplines have an interest in the subject of vision—psychology, physiology, ophthalmology, physics, photo-chemistry, genetics—and the subject has applications in very many different fields. It is too much to hope that all papers on vision can be channelled into a single journal, but if the best of them find their way into *Vision Research* this will be an immense gain to visual scientists, who at present have to search through a great variety of journals. It will also enhance the prestige of the science itself and stimulate more rapid progress in the subject. The first number has been dedicated very fittingly to Commander Dean Farnsworth, who was the guiding spirit when the project was first under discussion, but who died while the plans were still in the formative stage. A board of editors, under the chairmanship of Dr. T. Shipley, of Miami, is supported by a large honorary editorial advisory board drawn from some twenty different countries and representing the leading workers in the field. Success in a venture of this kind depends most of all, perhaps, on maintaining a high standard in the quality of the papers that are accepted for publication and on the quality of the publication itself. The first number has got away to a good start on both counts.

National Museums of Southern Rhodesia

IN the annual report of the National Museums of Southern Rhodesia for 1960 reference is made to the planning that has been undertaken for the provision of three new museums buildings at Salisbury, Bulawayo and Umtali (Pp. 22. Bulawayo, Salisbury, and Umtali: National Museums of Southern Rhodesia, 1961). To further these important projects the Administrative Section of the organization was moved to Salisbury as being better placed strategically to cover the three units. The move also relieved the Administrative Section, at a time of intensive planning, of the detailed work of any one unit. There have been several changes in the staff, and Colonel H. L. Boultbee, curator of the Queen Victoria Museum, has completed his contract with the Trustees. Much research has been undertaken and members of the staff contribute to an impressive list of publications.

Maccabaean Prize and Medal

ENTRIES are now invited for the 1962 Maccabaean Prize of twenty-five guineas and a Bronze Medal, which is awarded annually by the Faculty of the History of Medicine and Pharmacy of the Worshipful Society of Apothecaries of London. Competitors, who must be less than thirty years of age on March 15, 1962, will be required to submit before that date an essay of not more than 6,000 words on any subject connected with the history of medicine or pharmacy. Further details can be obtained from the honorary secretary of the Faculty, Dr. F. N. L. Poynter, The Wellcome Historical Medical Library, The Wellcome Building, Euston Road, London, N.W.1.

Plastics Institute Lectures on "Plastics"

THE Plastics Institute is again arranging a series of lectures on "Plastics", to be held at the City of London College, Moorgate, in the autumn. The lectures are of an introductory nature and are intended for non-technical staff. Applications for registration forms should be sent to the City of London College as soon as possible. The programme is as follows: "Types of Plastics", by Dr. C. A. Redfarn (October 2); "Plastics and the Chemical Industry", by Dr. E. S. Narracott (October 9); "The Structure of the Plastics Industry", by C. J. G. Stanley (October 16); "Plastics as Replacement Materials", by K. B. Bartlett (October 23); "Creation of New Markets by Plastics Materials", by C. W. Welch (October 30); "Plastics and Packaging", by Dr. G. Swift (November 6); "The Plastics Industry and the Rubber Industry", by J. A. Rhys (November 13); "The Future", by Dr. V. E. Yarsley (November 20).

University News: Leeds

THE following appointments have been announced: Dr. P. Grosberg, to a research chair of textile engineering in the Department of Textile Industries; Dr. P. R. Brook and Dr. G. A. Morrison, to be lecturers in the Department of Organic Chemistry; Mr. R. S. Davidson, formerly demonstrator in the Department, to be Brotherton Research Fellow in the Department of Organic Chemistry; Dr. I. G. Gass, to be lecturer in the Department of Geology; Mr. W. Houghton-Evans, to be lecturer in architectural engineering in the Department of Civil Engineering; Mr. M. Kirk, at present lecturer in the Department of Geography, to be lecturer in the Department of Social Studies; Mr. P. Levi, to be Bernard Hickson Fellow in the Department of Botany; Dr. G. A. Salmon, to be J. W. Wootton Research Fellow in the Department of Chemistry; Dr. Jean E. Wilkinson, to be Medical Research Council Research Fellow in the Department of Medicine.

The following grants and donations, among others, have been received: £1,000 from the Yorkshire Council of the British Empire Cancer Campaign, for the Department of Physical Chemistry; £15,000 a year for seven years from the Anglo-American Corporation of South Africa, Ltd., to continue the work of the Research Institute of African Geology, and

£13,362 during two years from the Department of Scientific and Industrial Research for an investigation into African rocks, for the Department of Geology; £1,000 from Courtaulds, Ltd., for the Department of Textile Industries; £1,000 during two years from Messrs. W. L. Ingle, Ltd., for the Procter Department of Food and Leather Science; £2,470 from the Ministry of Aviation for a research project in the Department of Metallurgy, Houldsworth School of Applied Science; £2,897 during two years from the Department of Scientific and Industrial Research for a research project in the Department of Biochemistry.

London

The following appointments have been announced: Prof. W. D. Gill, professor of geology and mineralogy in Trinity College, Dublin (see *Nature*, 172, 1082; 1953), to the chair of oil technology tenable at the Imperial College of Science and Technology; Mr. S. B. Watkins, head of the Department of Chemical Engineering at King's College, to the University readership in chemical engineering tenable at that College; Dr. Brian Abel-Smith, lecturer in social science at the London School of Economics and Political Science, to the University readership in social administration tenable at that School; Mr. L. P. Foldes, lecturer at the London School of Economics and Political Science, to the University readership in economics tenable at that School; Mr. Harry Townsend, lecturer at the London School of Economics and Political Science, has been appointed to the University readership in economics tenable at that School.

The title of professor of civil engineering has been conferred on Mr. J. K. T. L. Nash, in respect of his post at King's College; that of professor of powder technology has been conferred on Dr. H. E. Rose, in respect of his post at King's College; that of reader in economics on Mr. J. Wiseman, in respect of his post at the London School of Economics and Political Science; that of reader in engineering science on Dr. J. M. Zarek, in respect of his post at King's College; that of reader in pure mathematics on Dr. K. W. Gruenberg, in respect of his post at Queen Mary College.

Sheffield

Contributions to the University's Development Fund, the appeal for which was launched early in 1960, now total £480,975. While the major portion of the cost of the University's expansion is being borne by the Government, the University is required to make a contribution from its own funds towards the total allocation. It is to this end that the Fund will be used.

Announcements

H.M. The Queen has been pleased to approve the grant of a Charter to the British Institution of Radio Engineers. The grant of the Charter is recognition of the vital part played by radio and electronic engineering in modern times.

Mr. Ronald Beresford Dew has been appointed as visiting professor of industrial administration in the Faculty of Technology at the Manchester College of Science and Technology.

Dr. R. M. Laws, a principal scientific officer at the National Institute of Oceanography, Wormley, Surrey, has been appointed senior investigator in the Nuffield Unit of Tropical Animal Ecology, and will take up his duties at the Unit's field station at Mweya, Queen Elizabeth National Park, Uganda, in the autumn.

A summer school on corrosion has been arranged by the Metallurgy Department, Battersea College of Technology, and will be held during September 25–28. The topic will be "Corrosion Problems in the Electrical Power Industry". The course has been arranged in conjunction with the Corrosion Group of the Society of Chemical Industry, and will be given by independent lecturers. Enrolment forms can be obtained from the Secretary (Summer School), Battersea College of Technology, London, S.W.11.

The second conference on "Nuclear Reactor Chemistry" and the fifth conference on "Analytical Chemistry in Nuclear Reactor Technology" will be held in Gatlinburg, Tennessee, during October 10–12, under the sponsorship of Oak Ridge National Laboratory. Further information can be obtained from W. R. Grimes, Oak Ridge National Laboratory, P.O. Box X, Oak Ridge, Tennessee.

A special meeting of the Iron and Steel Institute of Great Britain and the Metallurgical Society of the American Institute of Mining, Metallurgical, and Petroleum Engineers is to be held in the United States and in Canada, and at the Metallurgical Society's annual congress in Detroit, during October 17–November 8. Further information can be obtained from K. Headlam-Morley, the Iron and Steel Institute, 4 Grosvenor Gardens, London, S.W.1.

A symposium on "Corrosion in the Nuclear Energy Industry" is being organized by the Société de Chimie Industrielle, 28 rue Saint-Dominique, Paris (7e), and will be held during October 19–20. The symposium will be concerned specifically with corrosion in sheath materials.

A symposium on the freeze-drying of foodstuffs will be held at the Department of Chemistry and Food Technology, Borough Polytechnic, London, during October 19–20. The symposium will deal with the development of freeze-drying techniques, a survey of the commercial equipment at present available and a discussion of the potentialities of the technique in various branches of the food industry. Nutritional aspects will also be included. Pilot plant and model freeze-drying equipment, samples of freeze-dried products and packaging materials will be on display. Further details can be obtained from the Secretary, Borough Polytechnic, Borough Road, London, S.E.1.

An interscience conference on "Antimicrobial Agents and Chemotherapy", sponsored by the American Society for Microbiology, is being held at the Hotel Commodore, New York City, during October 31–November 2. The first day will be devoted exclusively to infectious diseases, and the second and third to various aspects of antimicrobial agents, including their chemical evaluation. Further information can be obtained from the American Society for Microbiology, 19875 Mack Avenue, Detroit 36, Michigan.

The Research Fund of the Chemical Society provides grants for the assistance of research in all branches of chemistry. Applications for grants should be sent to the General Secretary, Chemical Society, Burlington House, Piccadilly, London, W.1, not later than November 15.

THE BRITISH HYDROMECHANICS RESEARCH ASSOCIATION

THE Laboratory of the British Hydromechanics Research Association at Harlow was open to visitors during June 13–15, when several hundred representatives from industry and the academic world saw details of the research carried out.

The Association specializes in the industrial application of fluid flow and serves a very wide range of industries. Some recent problems investigated are: the ventilation of mines; the design of centrifugal pumps; water hammer in pipe lines; rotary and reciprocating seals; cavitation; the hydraulic transport of solids; friction losses in pipe fittings; and hydraulic design of civil engineering structures. These problems are typical of the extensive interests of the Association. The numerous and apparently unrelated difficulties which arise in such industrial applications of fluid flow often have a fundamental similarity, and for this reason can sometimes be solved through the experience of specialists in fluid mechanics. The Association has been building up such a team in the twelve years since its formation, and can now offer members a pool of such specialized knowledge. Despite the name 'Hydro' in the title, the Association is interested in all fluids, both gaseous and liquid, and its membership includes such diverse industries as hydraulic machinery, instruments, paper, chemicals, aircraft, oil, brewing and the nationalized industries of coal, electricity and transport.

In its research on centrifugal pumps, the Association aims at establishing the sources of loss within a pump, which should lead to a better understanding of the way in which the efficiency of the pump can be improved. This work involves investigations of the Reynolds number effects on pump performance, the relation between impeller and volute characteristics and the overall machine characteristic, and the measurement of disk friction loss. The exhibits demonstrated the refined instruments necessary to study the distribution of velocity and pressure within a rotating impeller. This approach to the problem of centrifugal pump research will incidentally assist in the establishment of acceptable laws for the scaling up of model-pump tests, and for the use of air tests for the prediction of water-pump performance.

Of additional interest to those involved in the testing of hydraulic machinery was an exhibit summarizing the variety of items which have been studied relating to the design of pump test-circuits. These have included the use of guide vanes to prevent swirl and the development of a cascade design which will be more rigid than conventional cascades, and less sensitive to upstream-flow conditions. A 'pepper-pot' valve has also been developed which has the dual advantages of good control characteristics and low loss when fully open. For any circumstances where it is required to produce a good velocity distribution upstream of a test pump or flow-measuring device, a 'flow straightener' has been designed. This combines the features of a graded resistance and a honeycomb, and will reduce considerably the extent of straight pipe required upstream of a pump or flow-meter. A new understanding of the conditions of flow within a shielded pitot tube has enabled a simple shield configuration to be devised, which renders the pitot tube insensitive to the direction of flow over an angle of about 40°.

The Association has been able to assist in the solution of several mixing problems, and an exhibit devoted to this subject illustrated several different aspects of mixing. One of these is a study of the mixing of a jet of water discharged into a shallow lake. The purpose of the research was to check that adequate mixing took place when power-station cooling water was discharged into a lake, so as to avoid the risk of warm water re-circulating into the intakes, and to reduce the danger to the fish population. Another application of techniques of mixing is the development of an in-line blending unit which successfully mixes, in given proportions, fluids of widely differing viscosities. This uses an orifice designed to have a discharge coefficient which does not vary with Reynolds number.

Two recent items of research were on show, which were of particular interest to makers and users of control valves. The incidence of cavitation in such valves introduces risk of material damage to the valve seat, and, by increasing the loss through the valve, interferes with its effective operation as a control unit. The exhibit reminded makers and users of the importance of checking for cavitation, and showed the importance of a dimensionless 'cavitation number' in defining the incidence of cavitation. Research is also being undertaken on the oscillation of relief valves, a frequent source of trouble in hydraulic engineering. The model valve on show demonstrated that unstable oscillations could occur at several frequencies, depending on the damping.

The water-driven vacuum pump is a device familiar to laboratory workers, but it may not be appreciated that the same technique is becoming more widely used as an economic means of maintaining vacuum in power stations and chemical plant. The essential design features of these pumps were demonstrated with the aid of a transparent model, which showed the importance of ensuring good mixing between the driving fluid and the entrained gas.

When air is released under water from a line source a rising vertical current is induced which, when it reaches the surface, divides into two surface water currents. The windward side current is capable of breaking approaching waves, so that relatively calm water is found in the lee side of such a 'pneumatic breakwater'.

At the request of a Government research establishment, the British Hydromechanics Research Association has studied the relationship between air flow and jet velocity, and has found means of accounting for the effects of slip of the air bubbles.

The exhibits relating to models of civil-engineering structures and pump sumps demonstrated the increasing use of models to ensure the achievement of design requirements, and to devise modifications which could lead to economies in head loss.

For spillways, the function of the model is primarily to study the most suitable design of stilling basin to dissipate the energy of the water at the bottom of the structure. This aspect was illustrated by a model, at present being tested, of the spillway for the Sasuma Dam in Nairobi.

Models of the cooling-water intakes for the Sizewell nuclear power station were also on show. One, an air model, was being used to determine the head losses at the junctions between the intake shafts and tunnels. As a result of the tests made on this model, modifications to the hydraulic design which naturally had to be compatible with the structural engineering requirements have reduced the head losses due to the junctions by 40 per cent.

The diversity of interests of the Association was of advantage in this case, as the modifications were based on experience gained previously in the study of ventilation schemes of mines. These intakes will be located in a tidal estuary, and a water model has been constructed to examine the effects of tidal flow and tide-level on the flow and head loss in the intakes, and the possibilities of the formation of air entraining vortices.

The Association is also active in the rapidly expanding field of 'industrial hydraulics'. There are many problems involved in the design and utilization of high-pressure oil hydraulic machinery, and a particular example is the use of slipper pads to transmit the thrust from a swash plate to the pistons in an axial-piston pump. An analysis of the conditions for minimum power consumption of these slipper bearings has shown that the minimum occurs when the viscous drag loss is three times as large as the flow loss, although this ideal cannot always be attained as the resulting film gap would be too small. A new apparatus has been built to test slipper bearings under dynamic conditions.

Examples of machines embodying design features of this nature were seen in the form of two experimental power transmissions. One is for applications which require a rapidly variable speed, and is a 2 horse-power ball-piston pump/motor machine. The extremely low inertia of this unit is demonstrated by the fact that full reversal of rotation at 3,000 r.p.m. takes about 0·01 sec. The second exhibit was designed for a motor-vehicle drive where a prime requirement is high efficiency. This unit employs a differentially coupled pump and motor and has an efficiency exceeding 90 per cent, over a wide range of speed.

The Association has been active in work to ensure compatibility between a hydraulic system, and the hydraulic fluid. A rig was demonstrated for the evaluation of hydraulic brake fluids to study, over a wide range of temperatures, such factors as brake response, leakage, seal life and fluid deterioration. A committee has recently been formed to draw up a specification which will define adequately the properties required of a fluid to be used in particular applications.

Recently, the efforts of the Association in research on fluid sealing have been increased considerably by special contributions from members. This research is directed towards studying the physical processes involved in sealing in mechanical seals, stuffing boxes, and reciprocating shaft seals. A new test rig has been built to study the behaviour of mechanical seals at pressures up to 3,000 p.s.i. In particular, the rig will be used to investigate the possibility that the present limits on the pressure rating of this type of seal are due to mechanical distortion.

In reciprocating-shaft seals it has been found that the leakage is proportional to the square of the shaft speed, and independent of pressures above 1,000 p.s.i. The leakage increases and the friction decreases as the fluid viscosity is increased.

Although the exhibition was primarily of the present research work, an equally important function of the Association is to assist members in the solution of day-to-day problems involving fluid flow, and in issuing an *Abstract Bulletin* and technical reports which keep the membership in touch with the work carried out in other laboratories.

A problem common to all research associations is that of ensuring that the designers and development engineers, who will benefit most from the experience available at the laboratory, are kept informed of the service which is available. To this end, a mobile unit has been fitted out with exhibits demonstrating all the aspects of the work of the Association. The visits made so far by the unit, to member firms, have resulted in a fruitful interchange of ideas between the research staff of the Association and their colleagues in industry. S. T. Bonnington

BLOOD GROUPS OF ANIMALS OTHER THAN MAN

A CONFERENCE on "Blood Groups in Infra-human Species", organized by the New York Academy of Sciences, was held in New York during May 15–16. The programme of papers arranged by Drs. D. B. Amos and C. Choen very fully covered much present-day research on the identification of blood groups in animals other than man, and their use in a variety of pure and applied sciences. On the first day several papers described work with animals useful in medical research. Drs. R. D. Owen (California Institute of Technology) and D. R. Anderson (School of Aviation Medicine, Brooks Air Force Base, Texas) had collaborated on a study of blood groups in the rhesus monkey, with the object of providing markers for transplanted erythropoietic tissue in irradiated animals. Blood group systems in the dog had been thoroughly investigated by Drs. S. N. Swisher, L. E. Young and N. Trabold (Rochester School of Medicine, N.Y.), and used in experimentation of clinical interest. The rabbit is valuable in comparative research on hæmolytic disease of the new-born, and for this a knowledge of its blood groups was an essential pre-requisite. Dr. C. Cohen (Battelle Memorial Institute, Columbus, Ohio) pointed this out in his review paper, while making an eloquent plea for research workers to co-operate more closely in establishing nomenclature of blood group systems. Dr. Cohen also provided an illustration of the wider interest of the conference with his discussion of genetical aspects and natural selection. The usefulness of rats as laboratory animals was exemplified by the inclusion of three papers about them. Dr. R. D. Owen reported on genetic systems of antigens which had proved abundantly useful as tools in a variety of experimental studies, in particular of red cell chimærism following either parabiosis, embryonic injection or bone marrow injection after X-irradiation. The interest of Drs. A. E. Bogden and P. M. Aptekman (Biochemical Research Foundation, Newark, Delaware) was in inherited hæmagglutinogens of rats and their relationship to histocompatability factors. The presence or absence of one hæmagglutinogen determined growth or rejection of a tumour, and this system showed a number of other interesting parallels with the H-2 factors of mice. In a careful review paper, Dr. J. Palm (Wistar Institute, Philadelphia), described her own work with blood groups and histocompatibility factors of rats and related it to that of other investigators.

The first of three papers on mice was a review by Dr. D. B. Amos (Roswell Park Memorial Institute, Buffalo) in which most emphasis was naturally enough placed on the classical H-2 system of tissue and red cell antigens. A clear account of the serological and genetical complexity of this system was given. Drs. R. Basch and C. A. Stetson (Bellevue Medical Center, New York) followed with a description of results obtained using an assay method for those antigens of mice which elicit cytotoxin and hæmagglutinin production (antigens which they believe to be absolutely identical). A wide range of isoantigen activity—as judged by ability to absorb or neutralize cytotoxins—was found among various mouse tissues. Further detailed chemical results included the important finding that in liver homogenates antigenic activity was concentrated in the lysosome-rich fraction. Finally with mice, Dr. J. W. Goodman (Oak Ridge National Laboratory) described experiments in which blood or bone marrow, or both, were injected into irradiated mice, and the fate or establishment of the donor-type cells followed by serological means, either hæmolytic, for red cells, or cytotoxic, for lymphoid cells.

The remainder of the papers on the first day were of more general zoological interest, rather than specifically medical. Dr. J. Buettner-Janusch (Department of Anthropology, Yale) had studied the reactions of the red cells of various primates with various antisera prepared to agglutinate human A or B red cells. This work was intended primarily as an aid to anthropological investigations. In connexion with an entirely different sort of population study Dr. G. F. Ridgway (U.S. Bureau of Fisheries, Seattle) gave a fascinating account of the extremely difficult work involved in analysing blood groups of salmon and trout, primarily using isoimmunizations. Dr. W. H. Hildemann (University of California at Los Angeles) interpreted the term 'blood groups' in its very widest sense in considering the literature and his own work on genetic specificities of amphibians and reptiles. Individual differences in red cell antigens have been found in only five species; no intraspecific differences in serum proteins—as determined electrophoretically—have yet been found, although their existence as raw material for speciation must be postulated, in view of the known ordinal, familial or interspecific differences. In contrast to the above sparse evidence of diversity, tissue transplantation studies yielded evidence of a high degree of intraspecific antigenic diversity. The role of individual red cell antigens in speciation has of course been the main theme of the classical researches of Dr. M. R. Irwin *et al.* on pigeons and doves, and an authoritative account of this work was presented by Dr. D. H. Shaw (University of Wisconsin, Madison). Other aspects mentioned included the study of hybrid substances, and the use of blood-group factors as markers in somatic mutation work and in radiation chimæra research (the latter being Dr. Shaw's own particular contribution). The final paper on the first day was introduced humorously by the chairman as being about blood groups of bacteria. Dr. G. F. Springer (University of Pennsylvania, Philadelphia) had continued his previous work on the immune origin of so-called natural anti-human B antibodies —in which 'germ-free' chicks were inoculated with $E. coli\ O_{86}$—by studying the chemistry of the bacterial substances responsible for the cross-reactivity. Among various findings were striking resemblances to human blood group substances, as shown by the composition of the carbohydrates produced by hydrolysis.

The second day's programme was devoted almost entirely to blood-groups of animals of agricultural interest. The first of four papers on chickens was a general survey by Dr. D. G. Gilmour (School of Agriculture, Cambridge, England). One point especially emphasized was that the chicken has particular advantages as an experimental animal for the study of selective factors influencing the polymorphism of blood groups. Considerable evidence on this aspect was already available. Dr. W. E. Briles (De Kalb Agricultural Association, De Kalb, Illinois) followed with a meticulous account of experimental techniques leading to the discovery of further blood group systems in chickens, of which six were described, five probably new. Evidence on the relationship between B locus blood group genotypes of female parents, and the economic performance of their 'hybrid' offspring (four-way crosses of inbred lines), was presented by C. P. Allen (Hy-Line Poultry Farms, Johnston, Iowa). This paper was especially interesting, being indicative of the possibility of the application of blood groups in some systems of commercial poultry breeding. Work on a red cell agglutinogen of chickens identified by certain plant seed extracts was described by Drs. S. L. Scheinberg and R. P. Reckel (U.S. Department of Agriculture, Beltsville). The occurrence of this factor is both inherited and influenced by hormonal state, occurring in genetically competent females only on the onset of egg-laying. Pigs were the subject of two papers, the first being a very clear account of the state of knowledge of their blood groups by Dr. E. Andresen (Iowa State University, Ames), much of whose own work had been done at the Royal Veterinary and Agricultural College, Copenhagen. His interest was primarily in genetic studies, and to a lesser degree in hæmolytic disease of the new-born. This condition was the prime interest in the second paper on pigs by Drs. R. Saison and D. G. Ingram (Ontario Agricultural College, Guelph), who reported on some systems previously described, and other new ones. They also briefly mentioned studies of blood groups of mink.

The report on horse blood groups by Dr. D. Franks (Department of Pathology, Cambridge, England) was largely concerned with hæmolytic disease of the new-born foal, and included much important material of veterinary and comparative medical interest. Dr. Franks's suggested interpretation of some of his serological findings—variation in amount of antigens in different genotypes—as being due to a *cis-trans* position effect provoked one of the most lively discussions of the meeting.

The last afternoon session was opened by Dr. C. Stormont (University of California at Davis), who presented a highly competent and scholarly review of blood groups in cattle. In one cattle system, *J*, the antigenic substance is found in soluble form in various body fluids and tissues, and is absorbed on the red cells. This was the subject of a contribution by Dr. W. H. Stone (University of Wisconsin, Madison), who discussed physiological, genetical and chemical aspects. Dr. J. Gasparski (Polish Academy of Science) was unfortunately unable to attend the meeting, and his paper—on red cell antigens of the European bison identified by cattle blood typing reagents—was read for him. A definitive account of blood-group systems of sheep was given by Dr. B. A. Rasmusen (University of Illinois, Urbana), and the meeting concluded with a fascinating account, presented by Dr. A. Eyquem (Pasteur Institute, Paris), of blood group investigations by himself and Drs. L. Podliachouk and P. Millot. Species involved were chimpanzees, horses, mules, donkeys, sheep, pigs and cattle.

The papers described above are to be published as soon as possible in the *Annals of the New York Academy of Sciences*, and should remain definitive for some time to come. In addition, the meeting provided an excellent opportunity for exchange of opinions between workers in widely diverse fields, and there can have been few attending who did not acquire ideas for new approaches. Discussions were especially enlivened by the presence of some guests noted particularly for their research on human blood groups, among whom may be especially mentioned Drs. W. C. Boyd, S. D. Lawler, P. A. Levine and A. S. Wiener. Other activities associated with the meeting included an evening discussion meeting, which resolved to form an Immunogenetics Society of America, another evening discussion on blood-group nomenclature, and a most enjoyable dinner in honour of Dr. M. R. Irwin, arranged by some of his past students.

D. G. GILMOUR

DESIGN AND USE OF RESPIRATORS

A JOINT meeting of the Ergonomics Research Society and the British Occupational Hygiene Society at Porton on July 5 and 6 was devoted to the study of respirators. The Societies were welcomed by Dr. E. A. Perren, director of the Chemical Defence Experimental Establishment (C.D.E.E.). The first paper, by C. G. Trotman (C.D.E.E.), dealt with the history of the subject. Dust masks were much the oldest form of respirator but were not really significant until a performance standard for industrial dusts was established in 1933. Canister respirators for protection against industrial gases grew from the chlorine box respirator of the First World War. The Chemical Works Regulations of 1922 enforced the provision of respirators of an adequate standard; since then, systems of coding and testing respirators for practically all known industrial and agricultural hazards have been laid down.

R. G. Dorman (C.D.E.E.) discussed fibrous filters for protection against aerosol particles. Sizes near $0\cdot3\mu$ diameter are the most difficult to filter; collisions with filter fibres are less probable for particles having low inertia and small Brownian motion so that they tend to penetrate the filter relatively easily. Experimental demonstration of a minimum of filtration efficiency at a certain particle size proved the general validity of the theory of filter action. The resin–wool filter was described, which combined extremely low air-flow resistance with high efficiency, due to electrostatic action. Methylene blue and sodium aerosol testing, with flame photometer detection, were also discussed, and desirable standards of protection indicated.

F. A. P. Maggs (C.D.E.E.) gave an account of the removal of gases by activated charcoal. Adsorption is a matter of the surface area of the charcoal and the number of molecules of gas, so that a high molecular-weight gas is retained better than one having small molecules. The life-time of a respirator against volatile, low-molecular-weight vapours may be quite short and there is some difficulty about giving proper warning of incipient failure to the user.

J. E. Cotes (Medical Research Council Pneumoconiosis Research Unit) dealt with physiological aspects of respirator design, including breathing apparatus supplied with oxygen. Factors of importance included dead space, flow-resistance, vision, fit of face-piece, and leakage. In addition to protecting the wearer, breathing sets with closed circuit made it possible to help him in situations involving physiological stress by humidifying, cooling and adding oxygen to the air which he breathed.

The ergonomics of the respirator was dealt with by R. J. Shephard (C.D.E.E.), who described methods of assessing the loss of performance resulting from wearing respirators. Deterioration of specific functions was slight, and the expenditure of energy occasioned by dead space and resistance only amounted to a few per cent of maximum effort under average conditions. General discomfort, sweating and unusual activity, however, reduced tolerance unless the subject were adequately motivated.

The work of ventilation was analysed by E. A. Cooper (Department of Anæsthesia, Newcastle upon Tyne), who directed attention to the contrasting resistance laws which were relevant to laminar flow in filter beds and turbulent flow in pipes and valves; the latter rises much more rapidly with an increase in the velocity of breathing. By considering the mechanism of respiration and cardiorespiratory function it was possible to lay down allowable standards of resistance.

Respirators, besides being protective devices, have been used in physiological research since the days of Lavoisier. H. S. Wolff (Medical Research Council, Hampstead) dealt with such applications. Mouthpieces were often used in place of masks, for brief experiments, but were uncomfortable and promoted salivation. Masks were important for measuring expenditure of energy from consumption of oxygen; types produced for anæsthetics, for airmen and for gas-masks were commonly adapted for physiological research, and various measuring devices could be attached to them.

Communication between persons wearing breathing equipment was the subject of a paper by J. Ernsting and J. E. Gabb (Royal Air Force Institute of Aviation Medicine). The situation is complicated in aircraft by the effects of reduced pressure on auditory acuity. Speech gives rise to respiratory flow patterns which impose a severe strain on the flow capacity of respiratory equipment.

J. R. Carr (Royal Navy) spoke of the design of underwater breathing apparatus. The lungs of the user must be pressurized to the equivalent of the surrounding water, which results in a rapid increase with depth of the mass of gas consumed. Long endurance therefore necessitates either re-breathing or a surface supply of gas. Gases under pressure may affect man adversely, and psychological and physiological hazards may be introduced by limitations of the breathing set.

F. Lavenne and P. Leyh (Institut d'Hygiene des Mines, Hasselt, Belgium) compared the performance of two closed-circuit breathing sets, one working with compressed oxygen and the other with liquid air, and an open-circuit apparatus supplied with compressed air. Exercises performed at different temperatures showed that the inspired air temperature depended mainly on release of heat by absorption of carbon dioxide and was lowest in the open circuit apparatus. Light weight was an important point.

Industrial gas and dust masks were analysed by H. J. R. Letts (C.D.E.E.), who emphasized the influence on design of legislation requiring approved types. Dangers due to limitations of the absorbing medium are not serious, but the risk from leakage at the face-piece is significant and difficult to measure; a 10 per cent leakage due to physical activity was common, and wearability of a mask was an important attribute because of the user's tendency to avoid discomfort by discarding it. Leakage through the face-piece seems to be a fundamental limitation of the container respirator and may have to be avoided by electrically driven individual fan units.

The iron and steel industry uses respirators to a large extent, as was explained by J. Graham Jones (Richard Thomas and Baldwin, Ltd.). Major problems were carbon monoxide, from blast furnaces, and dust. For the former, only air-line masks had been successful, and compressed-air points were provided on furnace platforms. In the Fire Service, F. C. S. Shirling (Home Office) stated that respirators were useless, because of oxygen deficiency, and self-contained breathing sets were used which had a useful life up to 1 hr. An overriding factor in design was the necessity for instant availability.

The final session was conducted with Mr. A. C. Peacock (formerly of C.D.E.E.) in the chair, who also read a paper on the manufacture and testing of respirators. He suggested that it would be advantageous if users were to collaborate in producing a limited number of designs, which should be manufactured by a single organization.

S. T. Hermiston, R. F. Hounam and R. P. Rowlands (United Kingdom Atomic Energy Authority) listed the various types of apparatus for protecting people who handled radioactive substances. The problems encountered in other applications are here augmented by the necessity of decontaminating the appliances after use. For this reason, a worker is issued with a respirator from a pool instead of its being fitted to him individually, a practice which drew some criticisms.

The final application of respiratory devices discussed was the important one of mine rescue, by C. R. Senneck (Safety in Mines Research Establishment). A new closed-circuit liquid-oxygen set has outstanding performance; it weighs 33 lb. fully charged and gives cool dry air for more than 2 hr. During heavy work at 90° F., respiratory cooling of more than 1 kcal./min. is available and the resistance is only 1 cm. water at 300 l./min.; operation is automatic.

C. N. DAVIES

FOUR DECADES OF STATE FORESTRY IN GREAT BRITAIN

THE publication of the forty-first annual report of the Forestry Commission in Great Britain for the year ended September 30, 1960,* marks the first year of State forestry activity in its fifth decade of existence. In temperate countries it takes more than four decades to create new forests, a process which does not end with the planting of so many trees on so many acres. In the year 1959/60 the State planted 61,700 acres and private enterprise 36,900 acres, making a total of 98,600 acres. If this rate continues and if we assume that the average length of rotation, making allowance for the slow growth to be expected on much of the land being planted, is 80 years, then it would seem that the final wooded area will, in that time, amount to 8,000,000 acres plus 2,000,000 acres already existing, or 10,000,000 acres in all. If this is the avowed objective, the position at the moment is reasonably good. The competition for land in Great Britain has not prevented the Forestry Commission from adding during the year some 60,000 acres of plantable land to bring its total holding thereof to 1,618,400 acres. In describing the year's work it is interesting to find, however, that private forestry is placed before State forestry. This may be merely politeness, but things have certainly moved a long way since the last chairman expressed the view that private enterprise in forestry was doomed. It has greatly strengthened its position in recent years and the policy of paying grants in aid to the tune of £1,150,000 a year has given it a remarkable boost. The dedication of woodlands to productive forestry has advanced to the extent that the area of private woodlands eligible, or about to become eligible, for State aid is now 837,476 acres. There is thus quite a healthy balance between the managed woodlands of the State and those of the private owner. It is surely time to abolish, if possible, the needless complication of having two bases of dedication, for only two of the 562 schemes in operation are on basis II.

The report introduces to the public the concept of the 'working-plan', which is, in fact, a plan of management for the forest. It is defined as being "in effect, a blueprint for a forest or group of forests" and "a direction to succeeding generations of foresters ensuring that in all stages of development the basic objectives are kept clearly in mind". One might ask what is a blueprint ? Have British foresters become that mechanically minded ? In 1960 a new working-plan code came into operation. The prescribed format contains no fewer than 43 chapters, and, if the code is to be rigorously applied, it would appear that the technical staff will have even less time to undertake essential technical operations and may even be helping to dig its own grave.

---

* Forestry Commission. Forty-first Annual Report of the Forestry Commissioners for the Year ended 30th September, 1960. Pp. 69 + 9 plates. (London: H.M. Stationery Office, 1961.) 5s. net.

So far, the Forestry Commission has been able to sell all its felled material, which amounted in 1959–60 to 20·1 million hoppus feet from a total area of forest of 1,283,256 acres. This presumably included the 500,000 hoppus feet blown down, equivalent roughly to the growth on 10,000 acres. While the problem of marketing is easy in those forests near industrial centres it will become acute in the next decade or two in the more remote forests, the location of which can readily be seen from an examination of the maps provided with the report. Improved methods of exploitation and transport are receiving attention and may be the solution, involving greater use of machines. Too much machinery used in forestry operations will kill employment in the country and increase it in the towns, however, which runs counter to a policy of re-population of the former. The wide scatter of the State forestry operations can be seen from the maps mentioned. This adds greatly to the risk of fire. The cost of fire protection is a heavy item in the creation from scratch of pure coniferous forests and £273,000 was spent thereon in 1960. Out of a total area of 1,618,400 acres of forest, only 1,596 acres, or 0·1 per cent, were lost by fire, the greater part through an excess of zeal.

A paragraph describes what has been done to preserve the remnants of the natural pine forests which are owned by the Forestry Commission. It mentions "a broad belt of the eastern Highlands" where the native Scots pine is a dominant species. The meaning of this is obscure. It is claimed that investigations began in the early days of the Commission into methods of treatment of the natural stands it had acquired. Details are not given, but the investigations were of the most meagre description and the main method of treatment has unfortunately been to plant up the greater part of these areas with introduced exotic conifers. The attention being devoted to other important indigenous species, especially oak and birch, is woefully inadequate, even in the research programme.

Forest research is the subject of a separate annual report. A relatively large staff is engaged in this work but its organization is far from satisfactory. It has engaged in numerous projects, many of which seem to be of minor significance. The main aim of research should undoubtedly be the improvement of sylviculture. This remark owes its origin to a statement in the report that fertilizers have been applied from the air to checked spruce stands in Cornwall, with impressive results. For how long will these results last and what was the cost ? Much research work owes its origin to faulty sylviculture, and in the improvement in their sylviculture British foresters have a great deal to learn. Forestry in Britain has suffered from a lack of trained personnel of the higher ranks and still has a long and arduous task before it is to realize its main objectives.

Regarding the financial cost to Great Britain of the establishment and working of the Forestry Commission, this is an appropriate year in which to consider this, because, when the Commission was set up in 1919, it was claimed that it would be self-supporting in forty years' time. The total net sum spent since the start, after allowing for income other than Treasury grants, is £118,219,420, on which presumably some rate of interest is charged. Far from being now self-supporting, in 1960 payments were £13,930,162, of which only £3,130,639 was met by operational income from sales, etc. A Parliamentary vote of an additional £10,702,000 was still required. There is a somewhat naïve explanation of why forestry is not turning out to be the "counter to depopulation in the uplands" that it has for long been claimed to be. Almost any other industry could justify its existence by claiming that it gives indirect employment in other industries.

The manner of presentation of the Forestry Commission report is odd. The author of it is presumably the secretary of that body, but the report is signed by ten other persons and is presented to two Ministers in conformity with legislative requirements. To what extent each of the eleven persons in question takes responsibility for the contents remains uncertain. There is no minority report. Whether the two Ministers who receive it sit down and discuss it in detail, or whether each deals with it in turn, is doubtful. It should be mentioned, however, that the Forestry Commissioners can rely on advice from national committees, regional advisory committees, a Home-grown Timber Advisory Committee, a Committee on the Utilization of Home-grown Timber, a Mechanical Development Committee and an Advisory Committee on Forest Research. In all, between 150 and 200 persons are named in the report as having some say in the running of British forestry. This restricts the number of competent independent reviewers of their activities to a very few and makes their task invidious

M. L. ANDERSON

POTATO VIRUS DISEASES

ALTHOUGH conferences, especially those restricted to a particular subject (therefore small) can be very useful for providing opportunities for exchanging views, their proceedings are often superfluous. Most of the interesting information they contain has already appeared in scientific journals or in reviews as well. Recently, it has become customary to include at the end of each paper the discussion which it has stimulated, but most of it is trifling or irrelevant to the paper.

This criticism applies to the proceedings of the fourth conference on potato virus diseases, held at Braunschweig, during September 12–17, 1960*. As it is only three years since the last conference, it is not surprising that the twenty-three papers (175 pages) it contains have very few advances to report.

Recently, Dr. Stegwee discovered that potato leaf roll virus multiplies in the vector *Myzus persicae* and has now reported more evidence for this. Of special interest is the finding of P. Ehrhardt that infected aphids show significant decrease in oxygen consumption. V. Moericke discusses some electron micrographs of the salivary glands of *M. persicae*. (Unfortunately the micrographs are not reproduced.) Those from infected aphids contain rod-shaped particles (50 × 200 mμ) which are suspected to have some connexion with leaf roll virus if they are not the virus particles themselves.

* Biologische Bundesanstalt für Land- und Forstwirtschaft, Braunschweig. Proceedings of the Fourth Conference on Potato Virus Diseases, Braunschweig, 12–17 September, 1960. Edited by J. Brandes, R. Bartels, V. Völk and C. Wetter. Pp. 175. (Wageningen: H. Veenman and Zonen, N.V., 1961.)

The papers by C. Wetter and J. Brandes report some recent work at the Biologische Bundesanstalt, Braunschweig, Germany, which increases our scope for grouping viruses on serological relationships. Using Freund's adjuvant, antisera to viruses, having rod-shaped particles, were produced with precipitation titres of up to 1 : 500,000 (unusually high titres for viruses). With such antisera it has been possible to demonstrate serological relationships between viruses previously considered unrelated. Even more unexpected is the relationship found between viruses differing in particle-length such as between potato virus X (520 mμ) and white clover mosaic virus (480 mμ).

There are five papers on the resistance of potato varieties to virus infection, the inheritance of resistance and some practical aspects in testing for resistance. However, there is only one paper on field experiments. This may be the fault of the selection committee and not that this important kind of work is lacking.

In recent years soil-borne viruses are in the mode. In this respect the *Proceedings* are up to date, but of the several viruses discussed only potato rattle virus is appropriate to the conference. From the three papers attempting to review "some aspects" of virus research none contains anything new which has not been previously discussed in other review articles.

B. KASSANIS

CHROMOSOMES OF *NEUROSPORA*

RESEARCH workers at the University of Texas are investigating the genetic and nutritional simplicity of the red bread mould, *Neurospora*, to map the locations, on particular chromosomes, of the determinants of biochemical reactions by which particular substrates are metabolized for utilization in life processes. The work is expected to lead to a clearer definition of the gene.

The red bread mould *Neurospora* has long been regarded as one of the most useful of genetical experimental organisms. Pure strains can be multiplied a million-fold in a few days without genetic change. Each cell nucleus contains only a single set of genes, so recessive characters are not hidden by dominants. *Neurospora* can be grown in pure culture on a chemically known medium containing only sugar and a vitamin B (biotin) plus a few inorganic substances. In the natural state, the mould possesses the biochemical apparatus to make, from these simple materials, all the other constituents of its cells. Thus when a genetic element is disrupted experimentally by irradiation, the mutation may be expressed and mapped in terms of the measurable changes which occur in the simple nutritional requirements of the organism.

A large group of such nutritional mutations of *Neurospora* have been described by R. P. Wagner, C. E. Somers and A. Bergquist at the University of Texas in Austin. Plotting the distribution of the mutations on a map of *Neurospora* chromosomes, Wagner's group traced them all to a limited area of the fifth chromosome. Wagner's report is preliminary, but appears to record the first demonstration, in any organism with a single or double chromosome complement, of a direct relationship between one small segment of a single chromosome and a particular set of biochemical reactions. (Damage in the segment of chromosome affected directly the transformation of precursors of two important amino-acids—isoleucine and valine.)

The results also indicate a linear arrangement of the chromosomal material, with its active elements arranged to correspond to the order of sequence of the biochemical reactions it controls.

Wagner's work is supported by the Division of General Medical Sciences and the National Cancer Institute of the U.S. Department of Health, Education and Welfare. The publication *Highlights of Research Progress in General Medical Sciences*, 1960, presents a summary of Wagner's work and that of other investigators who are sponsored by the Division*.

A CONCEPT OF ATOMIC EXISTENCE

By PROF. W. H. WATSON
Department of Physics, University of Toronto

IN classical terms we have a manageable concept of physical existence. We represent things in a space-time map. Usually the processes by which recognizing, naming and surveying are accomplished are not shown in this map. Nevertheless, they could be, and whenever there is doubt or unclarity in their application, they are so represented for the purpose of clarifying representation. So long as the precision of representation does not approach the limits set by the Uncertainty Principle, all the apparatus and procedure just referred to can be used. We have confidence in ordinary language and rely on the training of physicists needed for applying it successfully in this context. The force of this consideration is illustrated in the skilful elaboration of classical explanation by Thirring in the first chapter of his *Principles of Quantum Electrodynamics*.

At the microphysical level, of course, there are physical impediments to applying ideas that we take for granted in the unformalized improvisation necessary in using classical mechanics. The purpose of this brief article is to expose one aspect of our thinking that can be liberated from the pre-suppositions inherent in our forms of speaking about physical representation.

The classical picture of radiation misleads us with a picture of 'something' coming out of the source like a bullet from a gun. But to particularize the thing a label cannot be used; to name it one must point to the events connected by it.

For example, we know that the creation of a β-particle by a nucleus is associated with a detectable event—the recoil of the nucleus; and we know also that the β-particle can be detected in a scintillation counter. In the absence of a physical interaction by which the particle could be 'observed' on the way, the emitting nucleus is connected with the detector in one jump. Observing it in between creates a different phenomenon.

Motion in quantum physics is a transformation from one event to a later one. With the events, somehow or other an existence is connected. Classically, we want to put a thing at each event. The phenomenon of interference shows that we have to associate the existence with both events. The connexion between the events is an atomic existence: it cannot be cut.

The events that are connected are, in fact, not point-instants, although we may for mathematical convenience represent them as such, subject, of course, to the limited precision allowed by the Uncertainty Principle in applying the representation. So long as the events are well separated in space and time, this limitation may be left out of account in discussing the existence of atomic entities. Our idea must depend on essentially classical supports, namely, the events observed and recorded by means of devices we can see and handle, and the substantiality of the objects on which we depend to observe.

So far as physical observation is concerned where interference is involved, there is no existence between the source event and the detection event. So the kinematic order of ordinary physical space-time does not correspond to spatial possibility for the individual atomic existence. Yet the existences connect pairs of events in ordinary physical space-time. When under the stimulus of the bullet analogy for radiation we think of things launched into space, we fail to appreciate that we are ordering independent possible atomic existences into a series with a common initiating event (or one fictitiously arranged to be so) and a variable terminating one. But to get to a particular termination, one does not go through intervening members of the series, unless there are physical effects actually occurring by which to label the track. This then bears a resemblance to classical observation of a moving object.

A particle of a radiation field connects an emission event with a detection event (and it may also involve other events). The existence at the emission event is the recoil, or some such change in the emitter that can be observed. A corresponding existence is established at the detector. These two events, as it were, bound the existence of a particle which is said to leave the source and enter the detector, and is thought of as moving in the intervening space. Provided that the representation is crude enough, this view is practically effective. If sharper representation is attempted, the classical view of motion and the attendant possibilities of interpolating observations that do not disturb the physical process of the motion being observed are no longer allowed. Only if we accept the transition between the two events at the source and detector as the existence of the particle concerned are we on safe ground in relation to the interference of probability. In so far as we do not need to bring into account the physical effect of distant objects, we have the entity localized in an extended region that includes both events—but then we cannot imagine it moving within the region in a classically acceptable sense. Only if we can interpose events at which physical interactions take place that can be observed is the picture of classical motion applicable. Thus motion in quantum mechanics with non-classical statistics is represented by a set of separate existences which overlap on our map, whereas what corresponds to the classical case is a series of consecutive jumps in a continuing existence. The distinction is shown in Fig. 1.

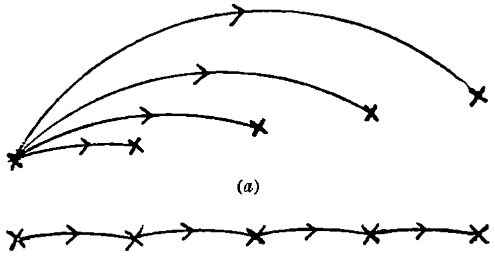

Fig. 1. The events being connected are marked ×. (a) Quantum connexions and overlapping existences; (b) classical series of consecutive jumps in a continuing existence

If we wish to represent the variable termination as a moving point governed by a continuous law of motion, we cannot have the point move in ordinary physical space because we must eliminate the intervening possibilities of ordinary physical space between source and detector.

We may exhibit in an elementary way how to achieve this. Consider the intersection of a rectangular axis triad ($OABC$) with a sphere of unit radius centred at O. Let the points of intersection be a, a', b, b', and c, c'. The directions Oa, Oa', Ob, Ob', Oc, Oc' stand for six distinct logical possibilities with which we are all familiar in ordinary language, namely, up-down, right-left, fore and aft. Vectors joining O to points (x) of the sphere other than a, a', b, b', c, c', do not stand for logical possibilities in this system. The vector Ox is a linear combination of the basis vectors Oa, Ob, Oc. (Here $Oa + Oa' = 0$, where + stands for the logical 'or'. So $Oa' = -Oa$. This is a necessary part of the logic of the system, since Oa and Oa' are mutually exclusive.) Ox does not represent one of the six logical possibilities, but it could represent a statistical combination of these possibilities, provided that we have regard to the laws of probability in establishing the representation. The mathematical elaboration of this is obvious, since the sum of the squares of the components of Ox is unity. The important point for my purpose here is that some points x are traversed by the representative point on the sphere in continuous transitions between pairs of the six logical elements of our system. A jump in the discrete system is then regarded as a continuous change according to some law which we have not yet specified. Once the continuous law is given, however, a track is specified on the sphere, and in going from Oa to Ob, for example, would pass continuously through points between Oa and Ob on the track.

This scheme of representation may be extended to a system of n possibilities and a representation in n-dimensional linear vector space. Imagine possibilities for existence on a lattice (h,k,l) where h, k and l are integers. We shall denote a variable point of the lattice by the integer triad (ξ, η, ζ). The mathematical identity:

$$u(\xi,\eta,\zeta) = \sum_{h,k,l} u(h,k,l)\ \delta_{\xi h}\delta_{\eta k}\delta_{\zeta l}$$

$0 \leqslant h,k,l \leqslant N$, where δ_{mn} is the Kronecker delta symbol, can be read as a vector equation in the space in which each

$$e_{hkl} = \delta_{\xi h}\delta_{\eta k}\delta_{\zeta l}$$

is a basis unit vector with $e_{hkl}\, e_{h'k'l'} = 0$ or 1 according as the corresponding primed and unprimed subscripts differ or agree. $u(h,k,l)$ is the hkl-component of the vector $u(\xi,\eta,\zeta)$; it may be a continuously variable number of absolute magnitude $\leqslant 1$, and indeed, corresponding to our previous spherical representation:

$$|u(\xi,\eta,\zeta)|^2 = \sum_{h,k,l} |u(h,k,l)|^2 = 1$$

Thus we have a N^3-dimensional linear vector space in which $u(\xi,\eta,\zeta)$ is represented as a vector.

Now consider displacement from $(0,0,0)$ to (a,b,c) on the lattice, that is, through points (ξ,η,ζ) for which the succession of co-ordinates is governed by the following rule (A); in each step only one of the integers, ξ,η,ζ, changes by unity while the other two remain unchanged. On the lattice, this resembles continuous motion in the continuum.

The corresponding transformation from $u(0,0,0)$ to $u(a,b,c)$ in the vector space proceeds via rotation from one co-ordinate axis to the next. But clearly, if u_{hkl} and $u_{h+1,k\,l}$ are positive:

$$u(\xi,\eta,\zeta) = u(h,k,l)\delta_{\xi h}\delta_{\eta k}\delta_{\zeta l} + u(h+1,k,l)\delta_{\xi h+1}\delta_{\eta h}\delta_{\zeta l}$$

represents a vector between e_{hkl} and $e_{h+1,kl}$. That is, whereas on the lattice we are concerned with integral steps between points of the lattice, in the vector space we can prescribe a continuous transition through the corresponding basis vectors in turn. Further, if we wish to allow only the integral connexion $(0,0,0) \rightarrow (a,b,c)$ on the lattice, we may prescribe a continuous one-parameter family of vectors bounded by $u(0,0,0)$ and $u(a,b,c)$, which includes none of the basis vectors except e_{000} and e_{abc}.

Thus this representation makes possible continuous transition (or motion) in the vector space corresponding to the connexion between two widely separated points of the lattice without requiring that intervening points of the lattice be traversed in accordance with the rule A.

Let us now pass to the representation of possibilities for existence in the continuum of physical space by letting N tend to infinity. The basis vectors now become:

$$\delta(\xi - x)\delta(\eta - y)\delta(\zeta - z)$$

corresponding to the spatial positions (x, y, z) and the sum over h, k, l is replaced by an integral over physical space. The integral connexion between two points of physical space, one corresponding to the source and the other to the detector of a physical particle, is represented in the vector space (which is now ∞-dimensional) by a continuous transition which need not require the vector to pass through any of the basis vectors.

In quantum mechanics the domain of numbers in which the components of the vectors vary is not the continuum of real numbers hitherto assumed above, but that of complex numbers (the grounds for this are given by H. Weyl in *Gruppentheorie und Quantenmechanik*, §4).

As an example of the law of continuous (unitary) transformation in the Hilbert space we may show the equation:

$$\frac{\hbar}{i}\frac{d\mathbf{x}}{dt} + H\mathbf{x} = 0$$

where $\mathbf{x}$ is the unitary vector and H is the Hermitian matrix for the energy (Weyl, *op. cit.*, §15).

In representing the emission of an atomic particle from a source, we should normally choose as the initial vector, consistent with our knowledge of the emitter, one of the characteristic outgoing spherical waves (an eigen function of the angular momentum). The location of the source is then indefinite to the extent determined by a momentum uncertainty equal to twice the momentum of the emitted particle. But when the source is observed to recoil, we have to choose a different vector to represent the outgoing particle: because of our enforced ignorance in the circumstances we have imagined, it cannot be an eigen vector of position or momentum, and it cannot be one of angular momentum. The particular vector judged appropriate for this representation carries the information needed with the dynamical law to determine the probability of the free particle being detected by a suitable detector placed in space to receive it. Thus the unitary vector associates a probability of detection with each point of physical space representing the position of a possible detector, and consequently with each member of the family of atomic existences that can be associated with the event in which the source recoils in a particular direction and 'a particle is emitted'.

If some diffracting or other physical system is interposed between source and detector, the 'state vector' for the particle is transformed by dynamical interaction and the new probability for detection at a given place is determined by the modulus squared of the component of the transformed vector in the functional direction, $\delta(x - x_D)\delta(y - y_D)\delta(z - z_D)$, (x_D,y_D,z_D) being the position of the detector.

In the functional space each possibility of existence is represented by a ray of 'unit length' from the origin. Only the particular axes that are eigen functions of 'the positional co-ordinates of the particle' correspond to the existences in physical space. Any other ray does not correspond to a point of physical space at all, because it involves in a sense every point of physical space. Thus in the functional space we have possibilities for existence that are not possibilities for existence in ordinary space. They can be interpreted statistically, however, and this is what quantum mechanics does.

In classical representation the physical thing is located in the event. This act in the representing process may stand for a quite different and more elaborate pattern of behaviour than merely marking the map, for it involves actual things and other processes. Whatever is done must be acceptable as a support for attaching to the event a name by which an existence inheres in the event. According to the conception presented here for atomic existence, we should attach the name to the atomic transition between source event and detection event. In a crude representation in which these events are not distinguishable, the name is in effect attached to a single event, as required by the classical representation with which we use the word 'existence' in ordinary language.

As to the existence of electrons in an atom or nucleons in a nucleus, physicists seem to be in no difficulty at the level of ordinary language, because the physical forces localize the particles sufficiently well to permit its unrefined use.

TIME-INTEGRATED MEASUREMENTS OF SUBMARINE IRRADIANCE

By RONALD CURRIE and LAURENCE DRAPER

National Institute of Oceanography, Wormley, Godalming, Surrey

IN the course of trials of a new type of self-recording integrating irradiance meter for use under water, some measurements of ecological interest have been made in two Scottish lochs.

The irradiance meters are designed to be suspended at a number of depths from a free-floating buoy and, in the course of a day, to integrate the total irradiance at these points. The final instruments will be designed to record the scalar irradiance in conjunction with measurements of the photosynthesis of the phytoplankton[1], but at present they have been used with flat-plate (cosine) collectors primarily to test the recording mechanism. No allowance has been made for this in presenting the results, and the integrated measurements do not take into consideration the alteration in angular distribution of the radiation as the day proceeds. Nevertheless, since the measurements were made under water, discrepancies from the true picture of downward irradiance are likely to be minimized through the effects of refraction at the surface and scattering by suspended particles in the water which tend to orientate the under-water radiation towards the vertical[2].

Through the courtesy and help of the director and staff of the Scottish Marine Biological Association Laboratory at Millport, we have been able to use these meters at two stations, one in Loch Striven and one in Loch Fyne. On both occasions the instruments were suspended at depths of 3, 5, 8·5 and 11 metres from sunrise to sunset in an unshaded position.

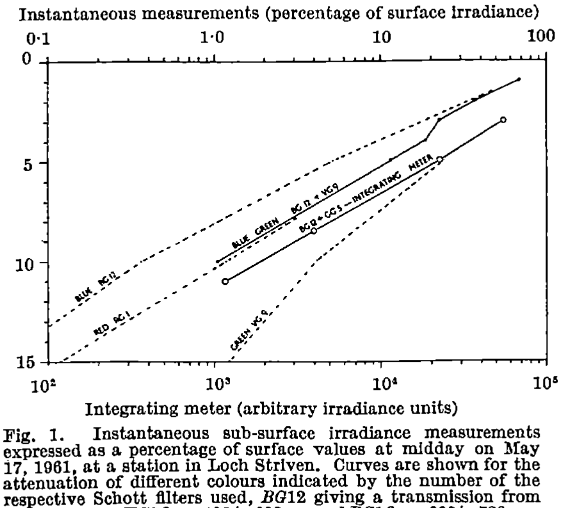

Fig. 1. Instantaneous sub-surface irradiance measurements expressed as a percentage of surface values at midday on May 17, 1961, at a station in Loch Striven. Curves are shown for the attenuation of different colours indicated by the number of the respective Schott filters used, *BG*12 giving a transmission from 860 to 480 mμ, *VG*9 from 480 to 600 mμ and *RG*1 from 600 to 720 mμ. The instantaneous measurements in the blue-green (*BG*12 + *VG*9) are compared with the integrated measurements (*BG*12 + *GG*5), the latter being expressed in arbitrary units

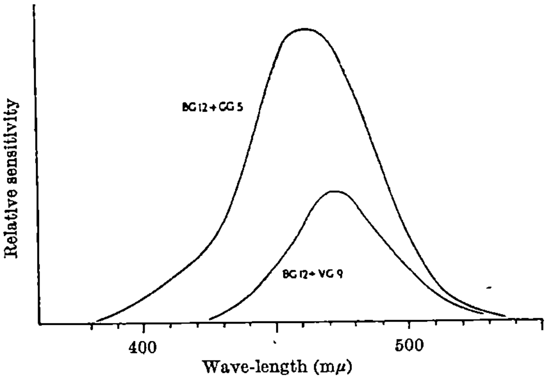

Fig. 2. The relative response of the cells and filter combinations used for blue-green instantaneous measurements (*BG*12 + *VG*9) and integrated measurements (*BG*12 + *GG*5)

Typical integrated measurements are shown in Fig. 1, where they are compared with instantaneous measurements which were made at midday on both occasions by the method recommended by Atkins *et al.*[3].

The integrating meters are fitted with a filter combination consisting of a 1-mm. thickness each of Schott *BG*12 and *GG*5 glass. The spectral sensitivity of these filters in conjunction with the photocell (Fig. 2) covers a 50-mμ band centred on the wave-length of maximum transmission in oceanic waters. This sensitivity lies close to that of the meters used for instantaneous attenuation measurements in the blue-green (Fig. 2) which were fitted with a combination of 2 mm. thicknesses of Schott *VG*9 and *BG*12 glasses.

Comparing the measurements in this part of the spectrum, it is clear that the decrease with depth of the irradiance integrated over a whole day follows a pattern very close to that of the attenuation measured instantaneously at midday. The corresponding attenuation coefficients 2·30 ($\log I_{\lambda,z} - \log I_{\lambda,(z+1)}$) (ref. 4) are shown in Table 1.

The close similarity between these measurements is very interesting, for it lends support to a method

Table 1. ATTENUATION COEFFICIENTS FOR INSTANTANEOUS MEASUREMENTS AND FOR THE IRRADIANCE OVER THE DURATION OF A DAYLIGHT DAY, IN THE 5–10 M. LAYER IN TWO SCOTTISH LOCHS

	Date	Instantaneous measurement Filters *BG*12 + *VG*9	Irradiance integrated over one day Filters *BG*12 + *GG*5
Loch Striven	May 17, 1961	0·482	0·493
Loch Fyne	May 18, 1961	0·532	0·559

commonly used in marine ecology in which the total radiant energy at different depths in the sea is computed by applying instantaneous attenuation measurements to an integrated record of the sea surface irradiance[5,6].

To the best of our knowledge these are the first direct measurements of sub-surface irradiance measured over a protracted period. While the agreement between these and the instantaneous measurements is good, it should be remembered that only the downward sub-surface irradiance has been considered, and that the measurements were made under ideal conditions with only slight sea-surface disturbance and a relatively high noon solar altitude (53°). We hope to extend these measurements to a consideration of scalar irradiation under water in diverse weather conditions.

Finally, an interesting feature of the optical characteristics of the water in these two lochs is demonstrated by the very high rate of attenuation of blue light (Fig. 1) measured with a Schott *BG*12 filter with its maximum transmission at about 430 mμ. This strongly selective absorption must only be ascribed to a strong yellowish coloration of the water, probably from dissolved organic substances like the "gelbstoff" of Kalle[7] and perhaps for the greater part originating from the humic acids in the fresh water inflow into these lochs.

A description of the integrating irradiance meters will be published shortly[8].

FIBROUS SILICA

Dr. WOLFGANG HALLER

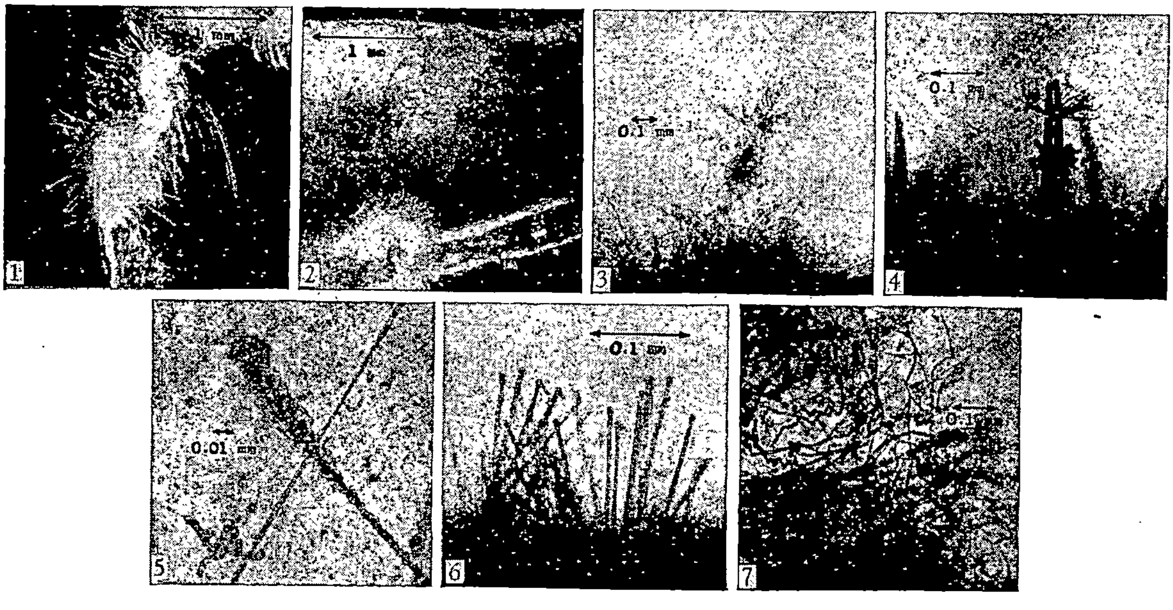
National Bureau of Standards, Washington 25, D.C.

FIBRES of silica were grown on electrically heated platinum surfaces by exposing the platinum target to nitrogen-diluted mixtures of silicon tetrafluoride and water vapour. Before striking the target, the mixture was passed through an electrically heated platinum tube maintained above the temperature of the target. The growth of the fibres on the target could be observed microscopically.

The fibres so obtained have circular cross-sections without any visible indication of faces. Diameters of fibres range from less than 1μ to 50μ. Their lengths range from 10μ to millimetres, and are limited mainly by the availability of growth space which has a homogeneous temperature field.

The refractive index of the fibres approximates the known refractive indices of vitreous silica (1·46) and is lower than the indices of any known forms of crystalline silica. Rotation of a fibre around its longitudinal axis reveals no optical anisotropy. Birefringency can be observed by rotating the fibres around axes perpendicular to their longitudinal axis. Because of the curvature of the fibres and the rather slight birefringency, it is difficult to distinguish if the birefringence extends uniformly over the full length or is segmentally modulated.

Figs. 1–7 illustrate typical forms of fibres. All fibres were grown at target temperatures of approximately 1,100° C. Lowering the target temperature



Figs. 1–7

produces colloidal silicious deposits, rather than fibres. Fibres start to grow straight or slightly curved, mostly originating from limited areas of the target. Clusters of this kind are shown in Figs. 1 and 2. The cluster in Fig. 1 originates from a corner of the platinum target. The cluster in Fig. 2 grew in a fan-shaped arrangement around the circumference of a thermocouple wire.

Frequently, secondary branching can be observed, as shown in Figs. 3 and 4. In these pictures the parental fibres are still visible. Another secondary growth occurs if fibres grow out of the optimal-temperatures field or if temperature fluctuations occur. In this case, the fibres terminate their growth with heads of opaque finely dispersed silica (Fig. 1) or the surface of the fibre becomes coated with colloidal silica (plume-shaped growth at the centre of Fig. 5).

Observation of fibre growth under the microscope conveys the impression that the fibres are in a plastic state. A fibre, having terminated its growth, may become shorter and thicker (Fig. 4) or may develop a spherical head at the point (Fig. 6). These spherical heads are as transparent as the rest of the fibre, while the colloidal deposits are opaque to light. The thickened fibre in Fig. 4 added later a mustachioed growth to its obese shape. Occasionally fibres suddenly change their direction of growth; the helical and zigzag shaped fibres shown in Fig. 7 owe their form to spontaneous angular bending of already grown, originally straight fibre segments. In addition to this drastic bending at distinct regions of the fibres, which is not reversible and which appears to be the product of flow or slip, the fibres constantly perform slight twisting and bending motions of synchronous character. Microscopical observation at growth temperature gives the impression of looking on a colony of water plants, drifting in a slow current. These motions are cyclic and reversible and may well be due to strains produced by fluctuations in the temperature field.

Spectrochemical analysis of the fibres produced only the emission lines of silicon. Water and fluorine contents were not determined, but are expected to be low since these compounds and their possible reaction products with silica have high vapour pressure at growth temperatures.

X-ray diffraction investigations of a multitude of fibres by the powder method showed amorphous bands plus faint but distinct diffraction lines, indicating a small degree of crystallinity. Selected fibres were mounted and investigated by single-crystal X-ray diffraction methods, but were only found to be completely amorphous.

A more detailed study of the fibre-forming conditions and more structural studies are being pursued. The most likely cause for the deposition of the silica into oblong, statistically and energetically unfavourable forms, is the action of some directing lattice force, although other directing mechanisms such as electrostatic agglomeration and thermal effects may be possible.

PYROLYSIS AND GAS-LIQUID CHROMATOGRAPHY ON THE MICROGRAM SCALE

By C. E. ROLAND JONES and A. F. MOYLES,

Research Department, Vinyl Products, Ltd., Butter Hill, Carshalton, Surrey

WE are now able to describe an improved pyrolyser unit for use in conjunction with a gas-liquid chromatograph.

Whereas the previous model[1], designed for use with a chromatograph equipped with a gas density balance detector[2], required a sample size of 2–3 mgm., the new unit, coupled with a Pye argon chromatograph, needs only 20–30 μgm. In this way the essential requirements for pyrolysis are better observed, in particular the criterion of a very thin sample film.

The improved pyrolyser (Fig. 1) consists of a 22-cm. length of 1 × 0·0015 single core 'Pyrotenax' so fashioned at the lower end that the sheath is partially cut away for 5 cm. and the insulating medium removed; the central conductor is shortened by 4 cm. and the end turned over to form a hook. A brass bush, 6 mm. long and 2·5 mm. in diameter, drilled to 20 wire gauge along its major axis and drilled and tapped to accept a 12 *BA* grub screw as illustrated, is brazed on to the inside of the cut-away at the bottom of the sheath. The filament is a 10 cm. length of 34 s.w.g. nichrome wire coiled to a diameter of 1·5 mm. (about 10 turns) one end of which is hooked over the end of the central conductor while the other is held captive in the brass bush after the length has been adjusted to give a resistance of 2 ohms. The upper end of the 'Pyrotenax' has the sheath removed for about 1·5 cm. to expose the central conductor and connexions are made in a conventional manner. The glass *T*-piece consists of a *B*.14 cone and a side entry for the carrier gas stream;

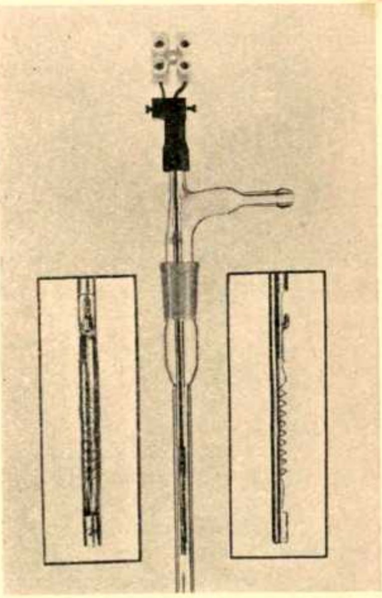


Fig. 1. General view of improved pyrolyser with details showing the filament mounting

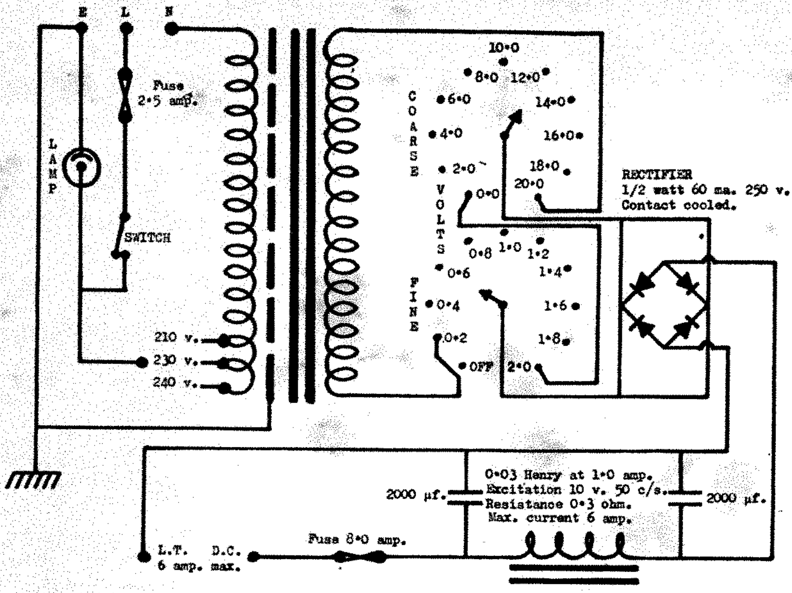

Fig. 2. Firing circuit for improved pyrolyser

the 'Pyrotenax' is held in position by means of a short length of thick-walled rubber tubing. The firing circuit (Fig. 2) is the low-tension section of a Radford 'Labpack'[3], which gives 0–22 V. by 0·2 V. steps up to a load of 6 amp.

The filament is calibrated by plotting applied potential versus temperature (measured under actual operating conditions with a Cambridge disappearing filament pyrometer).

The sample, in the form of a dilute solution or dispersion (about 1 per cent w/w concentration), is applied with a fine camel-hair brush to one or two coils toward the centre of the filament and dried under an infra-red lamp.

Comparison of the chromatograms obtained by pyrolysing a styrene homopolymer on both the milligram and the microgram scales (Fig. 3) is of interest, for the monomer yield rises from about 90 per cent on the milligram scale to near quantitative on the microgram scale. This, and the analogous behaviour of a methyl methacrylate homopolymer, are evidence for the occurrence of secondary reactions in the thicker film, probably due to the diffusion of fragments through the degrading polymer despite a reasonably short time of residence in the vicinity of the filament[4]. It is clearly advantageous, therefore, to work at the microgram-level.

The catalytic effect of the filament surface can be demonstrated at the milligram-level by comparing the pyrolyses of styrene and methyl methacrylate homopolymers using nichrome and gold-plated nichrome wires; the latter surface gives slightly simpler chromatograms. However, at the microgram-level no such differences are apparent when the pyrolyses are conducted on nichrome, gold-plated platinum and platinum filaments.

The versatility of the technique is illustrated by the following examples:

(i) Although many synthetic polymers are readily soluble in a wide range of organic solvents, it is often desirable to sample an aqueous polymer emulsion or a modified aqueous polymer emulsion direct without

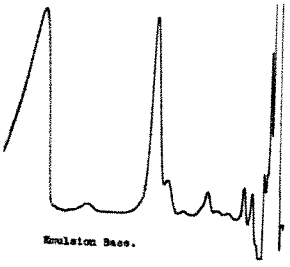
Emulsion Paint



Emulsion Base.

Fig. 4. Pyrolysis chromatograms of an emulsion paint and the emulsion base obtained by pyrolysing at 700° C. and chromatographing at 82° C. on a 4-ft. column prepared with 12½ per cent w/w poly-(ethylene glycol succinate) on 100–120 mesh acid-washed 'Celite' 545. Detector setting, 1,250 V. at maximum sensitivity. Argon carrier gas at 24 ml./min. Chart speed, 6 in./hr. Time of each analysis, 40 min.

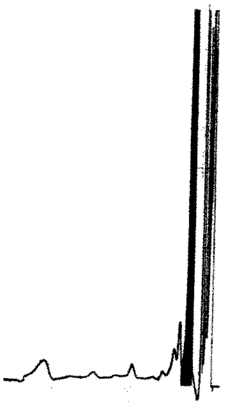


Fig. 5. Pyrolysis chromatogram of a sample of a motor-cycle fairing. The shaded peak is due to styrene. Conditions as for Fig. 4. Analysis time, 60 min.

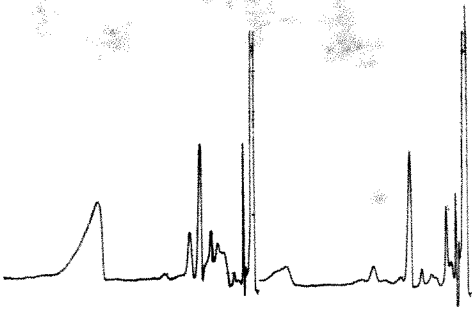

Fig. 6. Pyrolysis chromatograms of two samples of a silicone rubber. Sample 1 (left), sample 2 (right). Conditions as for Fig. 4. Time of each analysis, 50 min.

any preliminaries. This is exemplified in Fig. 4, which shows the characteristic identity of the polymer without separation from the inert constitutents.

(ii) Fig. 5 shows application to a fabricated polymer, a glass-fibre reinforced polyester, sampled by filing with a smooth Swiss file; the resultant powder mixed with 1 per cent w/w of gum tragacanth is slurried with water and then applied to the filament. Obviously, many materials may be treated in this way if they cannot be taken up into solution; a sample such as coal, for example, may be ground to an impalpable powder. It is desirable that filed or powdered samples should pass a 200 B.S.S. sieve.

(iii) Fig. 6 illustrates the pyrolyses of two specimens of a high-temperature silicone rubber, sampled by filing at – 70° C. (grinding at a somewhat lower temperature would be equally effective). Silicone rubber No. 1 retains its properties after prolonged use at 300° C., while silicone rubber No. 2 breaks down in use at 200° C. Quite clearly, there are chemical differences between the specimens.

We wish to thank the Directors of Vinyl Products, Ltd., for permission to publish this article, and we are indebted to Mr. G. E. J. Reynolds for helpful advice, and to Mr. M. Harrison for assistance with the practical work. Thanks are also due to Mr. F. Jackson, of the Woodall-Duckham Construction Co., Ltd., for the loan of a disappearing filament pyrometer.

EFFECT OF POLYVINYL ALCOHOL ON THE DISTRIBUTION OF IODINE-131 IN THE INTERNAL ORGANS, FLUIDS AND EXCRETA OF RABBITS

By H. F. NOWAK and J. KUCHARSKI

Department of Pathological Anatomy and Department of Medical Physics, Bialystok Medical Academy, Poland

ON the basis of experiments on mice given aqueous solutions of polyvinyl alcohol to drink in concentrations of 0·1 per cent–10 per cent for 210 days, it was found that this polymer is a non-toxic compound and causes a slight increase in the glycogen in the liver[1]. Experiments carried out with polyvinyl alcohol on rabbits showed that an 8 per cent solution at *p*H 7·3 and viscosity 1·7 possesses properties similar to plasma. This solution, when injected intravenously, brought about an excessive deposition of glycogen in the liver cells and Browicz-Kupfer cells during the first 4 weeks after injection, and, 3 months after injection, the liver glycogen content was similar to that of the controls. An increase in the number of normoblastic cells was noted in the marrow[2]. In experiments on *Tendipes* f. l. *plumosus* in aqueous solutions of polyvinyl alcohol, a 50 per cent increase in hæm was discovered[3]. Polyvinyl alcohol, administered intravenously to rabbits together with a shock dose of trypan blue, was effective in preventing the appearance of shock symptoms, and when administered to rabbits during the initial phase of shock, diminished the shock symptoms and thus prevented the death of the animals[4]. This polymer can, in addition to the above-mentioned properties, bind dyes and toxins and increase the kidney excretion coefficient of these substances.

In view of these properties, revealed in our previous experiments, our aim was to examine the effect of polyvinyl alcohol on the distribution of iodine-131 in animal organs.

The experiments were carried out on 20 rabbits of both sexes, weighing between 2·5 and 3 kgm. The rabbits were divided into two series, and each series was divided into two groups, (*a*) and (*b*). Rabbits 1–5, group (*a*), series I, were given 10-μc. iodine-131 intravenously in 10 ml. of physiological salt solution. Rabbits 6–10, group (*b*), series I, received 10 μc. iodine-131 in 10 ml. of polyvinyl alcohol, intravenously. All the rabbits of series I were killed 4 hr. after administration of iodine-131 with physiological salt solution and polyvinyl alcohol.

Rabbits 11–15, group (*a*), series II, received intravenous injections of 10 μc. iodine-131 in 10 ml. of physiological salt solution. Rabbits 16–20, group (*b*), series II, were given 10 μc. iodine-131 in polyvinyl alcohol, intravenously. All the rabbits of series II were killed 17 hr. after injection. Before killing the animals of both series, 3 ml. of blood were taken for testing. After centrifuging, the serum was separated from the morphological elements. When the rabbits had been killed, they were dissected. In order to detect radioactivity, the urine, fæces, bile, parenchymal organs, endocrinal glands, lymphatic nodes and marrow were taken for testing. All the tissues were dried at 80° C., after which they were triturated in a mortar, and the resulting powder put into specially prepared bags of polyvinyl chloride (as a protection against radiation). After weighing, the powder was placed under the mica end-window of the chamber in the Geiger–Müller, BAT-type counter and the number of impulses in a certain period of time was recorded.

At the same time, sections of organs were taken from each rabbit for histological examination. They were fixed in 6 per cent formalin solution and then,

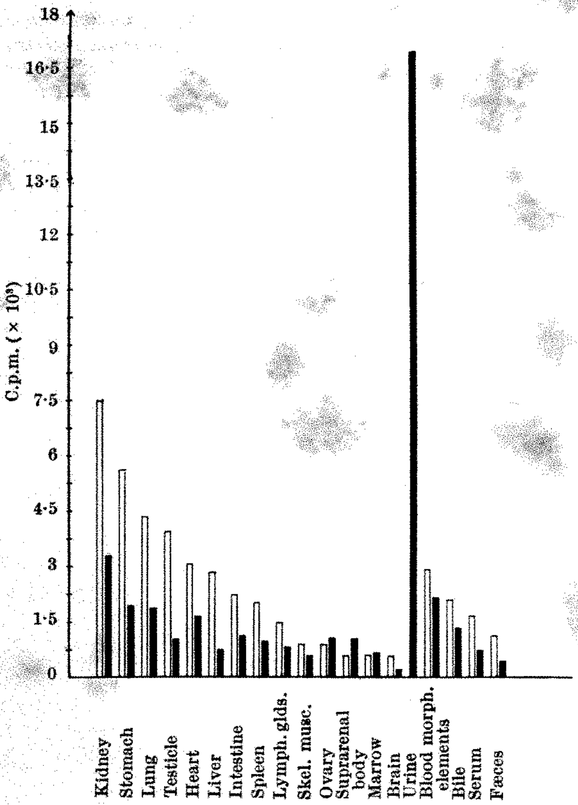

Fig. 1. Average findings from 5 rabbits injected intravenously with iodine-131 in physiological salt solution and from 5 rabbits given labelled iodine in 8 per cent aqueous solution of polyvinyl alcohol. The rabbits were killed 4 hr. after injection. The various columns represent activity of 1 gm. of dry mass of the organs of fluids, and of excreta, expressed in impulses per min. after intravenous injection of: white, iodine-131 in physiological salt; black, iodine-131 in polyvinyl alcohol

after dehydration, embedded in paraffin. The sections were stained with hæmatoxylin and eosin. The results are given in Figs. 1–3. The various columns represent 1 gm. of dry organic mass, fluids and excreta in counts per min. after intravenous injection of iodine-131 in physiological salt or polyvinyl alcohol. In calculating the radioactivity, self-absorption of radiation in the various samples was taken into consideration.

In the microscopical picture of the lungs of series I, group (*a*) rabbits, the walls of the alveoli were thickened. The epithelial cells of the alveoli were œdematous, with strongly acidophilic protoplasm. The mucous membrane of the bronchus showed hypertrophic and hyperplasic traits. The same changes were evident in the capillary vessels of the endothelium and the parabronchiole branch of the pulmonary artery. In the walls of the lung alveoli and in the blood vessel lumen, a great number of acidophilic leucocytes were seen. In the parabronchiole lymphatic nodules, hypertrophic and hyperplastic characteristics were observed.

The cardiac muscle displayed basophilic degeneration as well as single acidophilic leucocytes. The liver cells were enlarged, their trabecular outline obliterated and the nuclei of the Browicz–Kupfer cells clearly hyperchromatic. In the portal spaces, single acidophilic leucocytes were evident.

The bile duct epithelium showed hypertrophic characteristics. The epithelial cells of the straight kidney caniculi had a light-coloured protoplasm and gave the impression of being swollen. Among them, single acidophilic leucocytes were observed.

The suprarenal body displayed hypertrophy of the cortical layer with focal hyperplasia of the glomular layer. Single acidophilic leucocytes were seen in them. The stomach mucous membrane contained, in the superficial layer, single acidophilic cells. The lymphatic nodules of the appendix possessed hypertrophic characteristics and a considerable admixture of acidophilic cells. The glandular epithelium of the mucous membrane was grossly swollen and in places mucously degenerated.

In the rabbits of series II (*a*), killed 17 hr. after injection, there were considerably less acidophilic cells; on the other hand, mononuclear cells, similar in appearance to plasmatic cells, were increased in number.

In the sections of rabbit organs from series I and II (*b*) with polyvinyl alcohol, the acidophilic cells were less numerous than in group (*a*), with the physiological salt solution. The changes in the cells were absent, nor was there evidence of hyperplasia.

It was experimentally demonstrated that the rabbits which were given iodine-131 with polyvinyl alcohol were found to have a considerably different content of iodine-131 (in counts per min.) in their various organs, fluids and excreta, as compared with the rabbits given iodine-131 in physiological salt solution. In the thyroid gland, 4 hr. after administration of iodine-131 with polyvinyl alcohol, the radioactive iodine which accumulated was six times greater than in the thyroid of rabbits given iodine-131

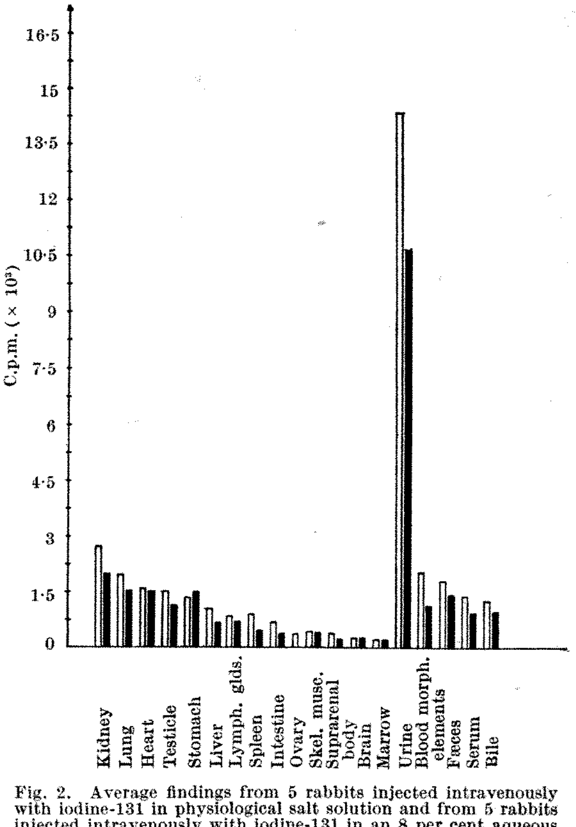

Fig. 2. Average findings from 5 rabbits injected intravenously with iodine-131 in physiological salt solution and from 5 rabbits injected intravenously with iodine-131 in an 8 per cent aqueous solution of polyvinyl alcohol. The rabbits were killed 17 hr. after injection. The various columns represent the activity of 1 gm. of dry mass of the organs, fluids or excreta expressed in impulses per min. after intravenous injection of: white, iodine-131 in physiological salt; black, iodine-131 in polyvinyl alcohol

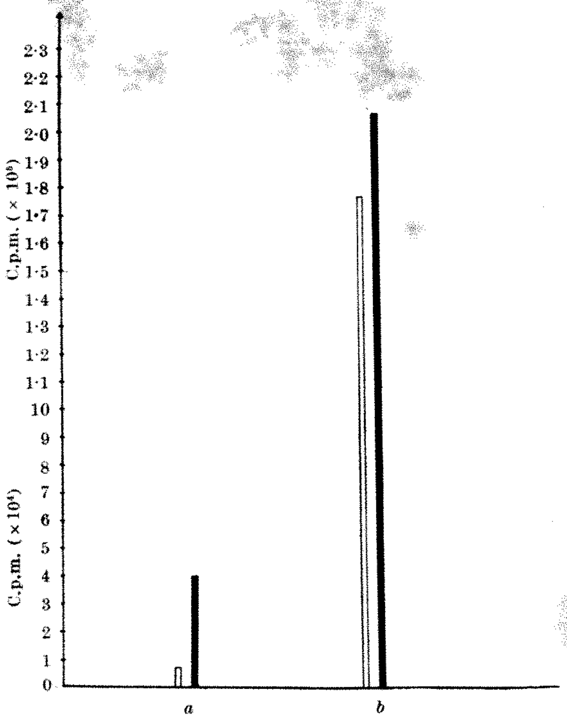

Fig. 3. Average findings from 5 rabbits which were given intravenous injections of iodine-131 in physiological salt solution and from 5 rabbits injected with iodine-131 in 8 per cent aqueous solution of polyvinyl alcohol. The rabbits were killed (*a*) 4 hr. after, (*b*) 17 hr. after injection. The various columns represent the activity of 1 gm. dry mass of degenerated thyroid, expressed in counts per min. after intravenous administration of: white, iodine-131 in physiological salt; black, iodine-131 in polyvinyl alcohol

with physiological salt solution. However, in the parenchymal organs of these rabbits, the amount of iodine-131 was less (by practically half) than that of the iodine-131 in the organs of the rabbits to which it was administered in physiological salt solution. After the injection of polyvinyl alcohol, the rabbits excreted urine in large amounts, especially during the first 4 hr. We recorded 1,650 counts per min. in the urine. Anuria was observed to occur during the first 4 hr. in the rabbits given iodine-131 with physiological salt solution. 17 hr. after injection of iodine-131 with polyvinyl alcohol, there was still more radioactivity to be found in the thyroid of these rabbits than in those which had received iodine-131 with physiological salt solution. Radioactive iodine accumulating in the parenchymal organs had a harmful effect on these organs, as was seen from the microscope pictures. Administration of iodine-131 with polyvinyl alcohol caused it to collect more rapidly in the parenchymal organs and thus the possibility of injury to these organs is considerably reduced.

In our experiments on rabbits, we also showed that the radioactive iodine given with polyvinyl alcohol and collected in the thyroid gland was six times greater than when given in physiological salt solution. Therefore, it can be concluded that doses of iodine may be reduced to a sixth, and thus the pathological changes in the parenchymal organs, occurring on administration of radioactive iodine, are even further diminished.

CONSTITUTION OF CELLULOSE MICROFIBRILS

By D. T. DENNIS and PROF. R. D. PRESTON, F.R.S.
Botany Department, University of Leeds

THE difficulty in isolating a native cellulose yielding glucose only on hydrolysis has long been recognized. Until comparatively recently the non-glucose sugars included in the hydrolysates of cellulose have been regarded as derived from residual unextracted hemicelluloses. The identification of cellulose with the microfibrils visible in the electron microscope, and the evidence that apparently pure microfibrillar material yield other sugars as well as glucose sometimes in amounts up to 50 per cent of the total sugar[1], show that the microfibrils are more complex than at first sight appeared. Since the microfibrils of, for example, *Rhodymenia* cellulose yield approximately equal amounts of glucose and xylose then they must at least contain molecular chains both of xylose and glucose. It is equally possible that the molecular chains may be mixed.

On various grounds it appears reasonable to suppose that the chains running down the centre of a microfibril form a core which is highly crystalline and that this core is clothed in a 'cortex' in which the chains, while still parallel, are not regularly spaced[2]. It is clearly possible to suggest further that this difference in the degree of crystallinity could be due to the presence in the cortex only of, for example, xylose residues, whether in the form of xylan chains or of mixed glucan-xylan. This possibility can to some extent be tested.

According to Ränby[3] and, later, Mukherjee and Woods[4] and others, cellulose microfibrils can under certain conditions be broken down to short rodlets which Ränby identifies with the crystallites—micelles—first suggested by Nägeli as the crystalline units in cellulose and later found necessary to explain some features of the X-ray diagram. If it were possible even approximately to associate these rodlets with short lengths of the crystalline core of the microfibril then analysis of these rodlets would serve to decide whether or not this central core is homogeneous. This article concerns the relevant observations.

Holocelluloses varying widely in hemicellulose content were prepared by the method of Jermyn and Isherwood[5]. With the exception of *Porphyra* these were treated with 4 per cent potassium hydroxide at 20° C. for 4 hr., a process known to remove most of the alkali-soluble hemicellulose with no damage to the microfibrils. Part of the residue was hydrolysed and the sugars identified as described by Cronshaw *et al.*[1]. The rest was treated with 2·5 *N* sulphuric acid at 100° C. for 24 hr. and washed until it formed a colloidal solution[3]. The dispersed phase

† From Cronshaw *et al.* (ref. 1).

was precipitated by the addition of a few drops of 0·1 *N* hydrochloric acid and the precipitate was washed by centrifugation into acetone and dried *in vacuo*. The resulting powder was hydrolysed and the constituent sugars determined both in this hydrolysate and in the acid extract. At each stage the material was examined by electron microscopy and by X-ray diffraction analysis.

The analysis of the celluloses after the various treatments is given in Table 1.

The colloidal celluloses contain at most only traces of non-glucose sugars even though these are abundant in the parent microfibrillar material.

Breakdown of microfibrils to rodlets therefore involves the removal of the bulk at least of non-glucose sugars. Since, as shown for phloem fibres by Ränby[3] and by Mukherjee and Woods[4] and for our material during the present investigation, the rodlets still yield the X-ray diagram of cellulose 1 the molecular chains cannot have been widely separated at any stage of extraction, and it seems likely that they represent in only slightly modified form the original central core of the microfibrils. The evidence suggests therefore that this crystalline core is cellulose in the 'true' sense (the 'eucellulose' of Myers and Preston[6]) and that the non-glucose sugars of the microfibrils are confined to the outer layers. This is of considerable importance both in terms of the mechanism whereby the microfibrils may be synthesized and because it means that even in celluloses containing a low percentage of non-glucose sugar residues the exclusion of these from the central core increases the proportion of them lying on the surface of the microfibrils to a level greater than might otherwise be expected. Except when so rigorously extracted that a cellulose preparation falls to a colloidal solution, its reactions with non-swelling material may be those of xylan and/or mannan and not of a glucan.

BREAKDOWN OF [2-^{14}C]-GLYCINE DURING PAPER CHROMATOGRAPHY

By A. K. HUGGINS and V. MOSES

Department of Chemical Pathology, King's College Hospital Medical School, Denmark Hill, S.E.5

IN the course of work on the metabolism of [2-^{14}C]-glycine by animal tissues, it has been observed that up to 40 per cent of the glycine may decompose with the formation of a number of radioactive substances when paper chromatograms are developed with phenol/water followed by *n*-butanol/propionic acid/water. It seems probable on the basis of chromatographic properties that the major breakdown product is neither glyoxylic nor glycollic acid. Unless quantitative measurements were made, the decomposition of glycine would not normally be detected, since the breakdown products did not give a positive ninhydrin reaction. Fowden[1] has reported losses of up to 30 per cent with glycine when chromatograms developed with phenol/water were dried with hot air. The influence on the rate of breakdown of glycine by various solvents, and of pre-treatment with oxalic acid of the paper used for chromatography, has been investigated.

[2-^{14}C]-glycine (0·1 μc.; 0·026 μmole) (Radiochemical Centre, Amersham, Bucks) was spotted on Whatman No. 4 filter paper, either untreated or previously immersed for 2 hr. in 1 per cent (w/v) oxalic acid, and then rinsed ten times during 48 hr. with distilled water. Chromatograms were run using the following solvent systems: (i) phenol (72 per cent w/w)/water (British Drug Houses phenol detached crystals B.P.C.); (ii) phenol (72 per cent w/w)/water, after distillation of the phenol over 0·1 per cent (w/w) aluminium turnings and 0·05 per cent (w/w) sodium bicarbonate[2]; (iii) *n*-butanol/propionic acid/water (45·9, 23·4, 30·6 per cent v/v)[3]; (iv) pyridine (80 per cent v/v)/water. One-dimensional chromatograms were run using each solvent on both oxalic acid-treated and untreated paper. Two-dimensional chromatograms were run on both types of paper using phenol/water or redistilled phenol/water followed by *n*-butanol/propionic acid/water, and again with the

solvents used in the reverse order. All chromatograms were dried for 24 hr. in a current of air at room temperature. Radioactive substances on the chromatograms were located by radioautography using 'Kodirex' No-Screen X-ray film (Kodak, Ltd.), and the radiocarbon in each compound was counted directly on the paper with an end-window Geiger–Müller tube[4] connected to a scaler.

The results are presented in Table 1, which reports the percentage of the carbon-14 on each developed chromatogram present in substances other than glycine. With phenol as the first solvent, there was streaking of radioactive material ahead of the glycine spot, suggesting breakdown of the glycine during chromatography. When this was followed by development in the second dimension with *n*-butanol/propionic acid/water, the streaked material was well separated from glycine (Fig. 1). In the acid solvent, the most radioactive area of the streaked material lay directly ahead of glycine, and it is probable that this represented glycine which decomposed while the chromatogram was being dried following development with phenol. Development in the acid solvent then separated this material from glycine. From the sum of the extent of glycine breakdown during development in phenol/water and in *n*-butanol/propionic acid/water, estimates were made of the amount of decomposition of glycine while phenol was being removed from the paper by aeration: these values are included in Table 1.

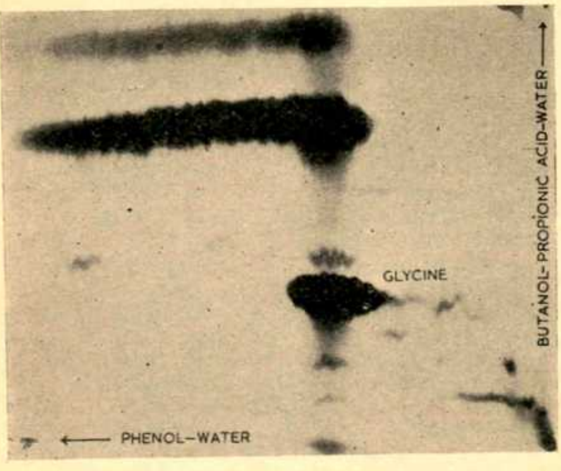

Fig. 1. Radioautogram of chromatogram of [2-^{14}C]glycine. Paper: Whatman No. 4 pretreated with oxalic acid. Solvents: phenol/water (first dimension); *n*-butanol/propionic acid/water (second dimension)

The breakdown of glycine during chromatography in *n*-butanol/propionic acid/water and in pyridine/water was low with untreated paper, and was reduced by treating the paper with oxalic acid. Breakdown in phenol/water was largely eliminated by distillation of the phenol, and there was a further improvement on treatment of the paper with oxalic acid, particularly with respect to the amount of breakdown of glycine during drying of the chromatogram. Development of the chromatogram with *n*-butanol/propionic acid/water prior to phenol/water exerted a protective effect on the decomposition of glycine in phenol, since the total breakdown after consecutive development in these two solvents was less than the sum of the observed breakdowns in each solvent separately.

Dr. J. R. Catch, Radiochemical Centre, Amersham, Bucks, has suggested that the extent of breakdown of glycine might be related to the very small quantities (2 µgm.) of the amino-acid which were applied to the paper. Three chromatograms were run using untreated paper, with phenol/water as the first solvent, and *n*-butanol/propionic acid/water as the second. [2-^{14}C]Glycine (0·1 µc.; 2 µgm.) was applied to the paper, either with no carrier or in the presence of 20 µgm. or 200 µgm. of unlabelled glycine. The percentages of the total carbon-14 not in glycine after development of the chromatograms were as follows: no carrier, 46·3; 20 µgm. of carrier, 39·4; 200 µgm. of carrier, 30·5. Thus, the breakdown of glycine was influenced by the total quantity of the amino-acid present on the chromatogram, but even large amounts of carrier provided partial protection only.

Fleming and Crosbie[5] have reported recently a non-enzymic transamination between glycine and glyoxylate which is catalysed by hydroxyl ions and inhibited at *p*H values less than 6. At *p*H 7 the reaction was catalysed by copper ions and inhibited by ethylenediamine tetraacetic acid. The *p*H of our paper, with and without treatment with oxalic acid, and before and after running in various solvents, is given in Table 2. Semi-quantitative determinations of the copper content of the solvents were performed by the phosphomolybdic acid method described by Feigl[6], and these values are reported in Table 3. It appears

Table 2. COMPARISON OF *p*H OF OXALIC ACID-TREATED AND UNTREATED PAPER BEFORE AND AFTER DEVELOPMENT IN EACH SOLVENT (Abbreviations as for Table 1)

Table 3. COPPER CONTENT AND *p*H OF SOLVENTS (Abbreviations as in Table 1)

Solvent	*p*H	Approx. copper content (μgm./ml.)
Ph.	4·8	20
Redist.-Ph.	4·8	20
But.-Prop.	2·5	10
Pyr.	9·2	0

from these results that the copper content of the solvents is not an important factor affecting glycine breakdown during chromatography, since there was no detectable difference in the amounts of copper present in the phenol before and after distillation; yet the extent of glycine breakdown was greatly reduced by distillation. The *p*H of the paper and of the solvents would seem to be of greater significance, as the degree of glycine breakdown on oxalic acid-treated paper (*p*H 4·9) was always less than with untreated paper (*p*H 6·7), even when pyridine/water (*p*H 9·2) was used as the solvent. The protective effect on glycine of developing the chromatogram first in the acid solvent is probably due to the incomplete removal of the acid during drying in air, resulting in a low *p*H of the paper after development in this solvent.

We have some evidence that similar chromatographic considerations may also operate in the case of other amino-acids, particularly L-[^{14}C]glutamic acid, and it would therefore appear advisable for the chromatography of amino-acids involving phenol as a solvent constituent to use an acid paper and to purify the phenol by distillation. Pretreatment of the paper with oxalic acid may also be beneficial as a result of binding any copper ions which may be present.

We wish to thank the Medical Research Council and the Empire Rheumatism Council for grants toward the cost of this work.

PHARMACOLOGICAL CHARACTERIZATION OF THE OXYTOCIC PEPTIDES IN THE PITUITARY OF A MARINE TELEOST FISH (*POLLACHIUS VIRENS*)

By PROF. H. HELLER and B. T. PICKERING
Department of Pharmacology, The University, Bristol
AND
J. MAETZ and F. MOREL
Departement de Biologie, Commissariat a l'énergie atomique, Saclay, Gif-sur-Yvette, Seine et Oise, France

PITUITARY extracts from teleost fishes have been shown to contain at least two oxytocic substances[1,2]. In the pollock or pollack (*Pollachius virens*) one of these substances has been identified as arginine^{8}–oxytocin (arginine vasotocin) by amino-acid analysis[2,3]. Arginine^{8}–oxytocin has also been chemically characterized in neurohypophysial extracts from frog[4] and chicken[5]. Chromatographic[2] and pharmacological[2,6] evidence has been advanced for the presence of arginine^{8}–oxytocin in the neurohypophysis of reptiles as well as in that of other amphibians and birds.

The second oxytocic principle found in pollock pituitary extracts was found to have many of the properties of oxytocin. Relative to its oxytocic potency, it showed very weak antidiuretic activity and, like oxytocin, had a much lower frog water balance activity than vasotocin[1]. When chromatographed on paper in butanol / acetic acid / water (4 : 1 : 5) (refs. 1 and 2) or eluted from a column of 'Amberlite *CG*-50' (ref. 2) it was found in the same position as oxytocin.

The 'second' oxytocic peptide in pollock pituitary extracts has now been compared with oxytocin ('Syntocinon', Sandoz) by further pharmacological tests. The sample of peptide used was prepared by paper chromatography of the material obtained from the region of oxytocin when pollock pituitary extract was eluted from a column of 'Amberlite *CG*-50' as in ref. 2. The active eluate from the paper chromatogram was freeze-dried and the resulting solid dissolved in 0·25 per cent acetic acid containing 0·5 per cent chlorbutol as preservative. This solution was used in all the biological assays described here.

The following tests were performed (the same batch of 'Syntocinon' = synthetic oxytocin, was used as standard throughout): (*a*) *Isolated rat uterus assay with and without magnesium:* Munsick[7] has shown that the action of many synthetic analogues of oxytocin on the isolated rat uterus is potentiated by the presence of magnesium in the suspension fluid. He showed also that the degree of potentiation varied from one peptide to the other. Accordingly, the unidentified pollock peptide was assayed on rat uteri suspended in either Munsick's[7] modified van Dyke–Hastings solution[8] without magnesium ions or in the same solution containing 0·5 m*M* Mg^{++}/l. The solution of the pollock peptide had a potency of 7 *U*/ml. in the absence of magnesium, but in the presence of this ion its potency was increased to

28 *U*/ml. Since 'Syntocinon' was the reference standard in both sets of assays, the increase in potency of the pollock peptide clearly differentiates it from oxytocin. (*b*) *Avian depressor assay*[9] *:* Estimations of the potency of the pollock peptide by this method gave a mean of 16·3 *U*/ml. compared with 7 *U*/ml. in assays on the isolated rat uterus without magnesium. (*c*) *Effect on sodium transport through the isolated frog skin* (natriferic activity[10]): unlike oxytocin, the unknown pollock peptide almost completely lacks the power to stimulate the sodium current produced by *Rana esculenta* skin *in vitro*. The mean natriferic potency was found to be 350 m*U*/ml. or 1/20 of the oxytocic activity. (*d*) *Effect on water movement through isolated frog bladder* (gravimetric assay[11,12]): as compared with oxytocin, the second pollock principle exhibited only a slight enhancing effect on the osmotic permeability of the *Rana esculenta* bladder. The mean activity was 750 m*U*/ml. or 1/9 of the oxytocic activity. (*e*) *Effect on water movement through the isolated frog skin* (volumetric assay[13]): The potency of the unidentified pollock peptide to enhance the net water flux through the isolated skin of *Rana esculenta* was very low, that is, about 350 m*U*/ml. or 1/20 of the oxytocic activity. (*f*) *Effect on water uptake by intact frogs:* in one *in vivo* experiment (21 animals) on *Rana esculenta*, the water-balance activity of the solution containing the unidentified pollock peptide was found to be less than 1 *U*/ml., that is, its potency in this test was less than 1/7 of that in assays on the rat uterus without magnesium ions. Low sensitivity of 'winter frogs' prevented further experiments.

The low potency of the unknown 'second' pollock oxytocic principle in all the amphibian tests is in striking contrast to the high potency shown by the 'first' oxytocic principle which has been chemically characterized as arginine^{8}–oxytocin[2,3]. Compared with oxytocin, for example, the latter was found in a few preliminary experiments to be about 20 times more potent on the sodium transport across frog skin and 200 times more active on the water movement through the isolated frog bladder. It was already known to be about fifty times more active in the frog water balance test *in vivo*[2].

Fig. 1 shows the difference in the potencies of the two oxytocic principles found in pollock pituitary extracts with reference to their action on sodium transport across frog skin.

The effect of oxytocin on the renal water excretion of rats varies according to the conditions of the experiment[14,15], but it has been shown that the hormone has a weak antidiuretic action in intact rats with a high water load. Assayed against 'Pitressin', 'Syntocinon' was found to have an antidiuretic activity corresponding to 1·1 per cent of its oxytocic potency[15]. When the unidentified pollock peptide solution was compared with 'Pitressin', its antidiuretic action was equal to a mean of 13 m*U*/ml. or to 0·2 per cent of its oxytocic activity.

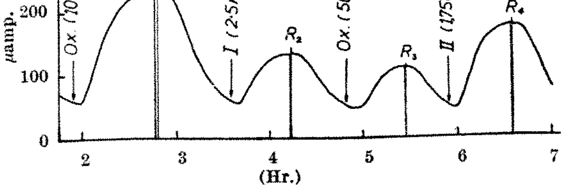

Fig. 1. Comparison of the effects of the two oxytocic pollock peptides and of oxytocin on the 'sodium current' (ref. 10) produced by frog skin. Ordinate: 'short circuited current' (in μamp.); abscissa: time, hr. Peptides added at arrows (in brackets: oxytocic = rat uterus activity). *Ox* = synthetic oxytocin; *R* = rinsing; I = the first oxytocic principle characterized as arginine^{8}–oxytocin. Note that it was about 20 times *more* potent than oxytocin. II = The second oxytocic principle. Note that it was about 20 times *less* potent than oxytocin

In a few preliminary antidiuretic assays[16] on *Rana esculenta* the antidiuretic activity of the unknown pollock peptide was likewise found to be very weak, while the 'first' oxytocic peptide showed a high antidiuretic activity similar to that of arginine^{8}– or lysine^{8}–oxytocin.

Table 1 shows the 'pharmacological spectrum' of the solution containing the unidentified oxytocic peptide in pollock pituitary extracts. The standard in each of the assays shown was synthetic oxytocin ('Syntocinon'). If, therefore, the pollock peptide had been identical with oxytocin, the activity ratio (last column of the table) would have been unity in each type of assay. The fact that all the assays on amphibians gave activity ratios very much less than unity indicates that oxytocin, if present at all, could only have been present in very small amounts.

Table 1. POTENCY OF THE UNIDENTIFIED ('SECOND') OXYTOCIC POLLOCK PEPTIDE ASSAYED AGAINST OXYTOCIN ('SYNTOCINON', SANDOZ) (Note that, by definition, the activity ratios would be 1, had the unknown substance been oxytocin)

Assay method	Potency (*U*/ml.)	Ratio of activity to rat uterus ($-Mg^{++}$) potency
Rat uterus without Mg^{++}	7	1
Rat uterus with 0·5 m*M* Mg^{++}/l.	28	4
Chicken blood pressure	16·3	2·3
Natriferic activity (isolated frog skin)	0·35	0·05
Water-balance activity (isolated frog skin)	~0·35	~0·05
Water-balance activity (isolated frog bladder)	0·75	0·11
Water-balance activity (intact frog)	<1	<0·15

Until the unknown peptide is completely purified, it cannot be excluded that the preparation used in the present investigation contained other very similar peptides. However, the results presented are sufficient to demonstrate that teleost pituitary glands may contain not only arginine^{8}–oxytocin (arginine vasotocin) but also another oxytocic peptide not found in the neurohypophysis of mammals. It would thus appear that the diversity of neurohypophysial active peptides in the vertebrate phylum is greater than hitherto assumed.

EVIDENCE OF A 'HUNGER MOTIVATIONAL' SYSTEM IN THE LATERAL HYPOTHALAMUS OF THE RAT

By Dr. P. J. MORGANE
Department of Physiology, University of Tennessee Medical School, Memphis 3

MUCH interest has recently been focused on the higher nervous control of food and water intake, particularly in the hypothalamic 'centres' concerned with the mechanisms of 'feeding' and 'satiety'. Several investigations[1-5] have tended to stress the importance of longitudinal hypothalamic fibre trajectories, especially the medial forebrain bundle, as being intimately involved in the motivation of feeding and drinking behaviour. Thus, Olds[4] classifies the lateral hypothalamic area along the medial forebrain bundle as a part of his 'reward' or 'pleasure' system, stimulation of which is 'preferred' by a hungry animal to actual feeding. Miller[6] has consistently found that stimulation of the lateral hypothalamic area in the perifornical area elicits feeding and drinking responses in satiated rats. His work indicates that the feeding and drinking areas are largely co-extensive with drinking responses slightly more prominent from the dorsal perifornical area. Miller has also shown that this stimulation evokes several properties of actual 'hunger' in that it would motivate learned food-seeking responses. Grossman[7], using the implanted cannula technique, has shown that injection of crystalline adrenergic substances into the peri- and supra-fornical areas elicits feeding in satiated animals and that acetylcholine injection caused water-sated animals to consume significantly more water. Furthermore, hungry rats would actually leave food, and drink water following acetylcholine injections.

In earlier experiments[8,9] I have shown that the medial forebrain bundle is not a crucial system in the effectuation of spontaneous feeding and drinking behaviour, since lesions in this bundle, singly and in combinations, anterior and/or posterior to the level of the 'feeding centre' did not chronically affect the intake of food or water. Only with lesions at the level of the ventromedial nuclei was the lateral hypothalamic syndrome of adipsia and aphagia produced, and these effects were radically different in nature depending on whether the lesions were in the mid-lateral or far-lateral hypothalamus. Mid-laterally lesioned animals showed a 'reversible' type of aphagia and adipsia, while far-laterally lesioned animals showed a more drastic 'failure' with no reversal tendencies even when carried 45 days on tube feedings. It was postulated that crossing fibre systems, mostly pallidofugal, were the critical elements in the organization of the feeding and drinking 'centres' since these were interrupted after far-lateral lesions but not after mid-lateral or perifornical lesions. The more drastic downhill course in the animals lesioned in the far-lateral hypothalamic area correlated well with degeneration in the pallidofugal fibre systems. Furthermore, it was shown afterwards[10] that lesions directed to the origins of these systems in the internal segments of the globi pallidi reproduced faithfully the far-lateral hypothalamic syndrome.

I have also shown[11] that the lateral hypothalamic area seems to be organized in a complex manner into a more medial 'hunger motivational' system and a far-lateral 'metabolic' system[11]. Animals lesioned medially and perifornically showed predominantly a 'motivational' failure toward food and water since this adipsic–aphagic state was easily reversible after forced feedings depending on the extent of the lesion. Some of these medially lesioned animals showed adipsic and aphagic reversal even when given special positively motivating foods such as chocolates, malts, etc., and it is now thought that all these animals are potentially reversible with proper post-operative support. On the other hand, far-laterally lesioned animals with pallidofugal fibre degeneration or animals with lesions in the pallida themselves are not so easily reversed. In my experience with 15 far-laterally lesioned rats supported by tube feeding, 5 died in spite of this treatment, 9 died of aphagia and adipsia after the tube feedings were discontinued (between 12 and 45 days post-operatively in the various animals), and only 1 showed reversal (resumption of spontaneous feeding and drinking behaviour) after 43 days of tube support. Of 9 animals lesioned in the pallida, 5 died during tube support while the remaining 4 reverted to adipsia and aphagia after tube removals (20–48 days) and died shortly thereafter. Five other animals lesioned in the pallida and not given tube support all died of aphagia and adipsia with food and water freely available. Thus, the far-laterally lesioned animals were not merely showing 'motivational inertia' to water and food but some additional defect not compensated for by actually delivering food and water to the gastro-intestinal tract. I have termed this a 'metabolic' failure as opposed to the purely 'motivational' failures of the mid-lateral and perifornically lesioned animals[10].

In the present experiments bipolar stainless-steel electrodes 0·20 mm. in diameter were implanted stereotaxically in the lateral and dorsal perifornical areas as well as in the far-lateral hypothalamic area. The stereotaxic co-ordinates used were: anterior planes 5·8–4·9 of DeGroot[12], parasagittal planes 1·0–1·7 for the perifornical implantations and 1·7–2·5 for the far-lateral implantations, and horizontal planes −1·5 to −3·0. This range of loci corresponded to several areas immediately around the fornix columns and in the areas of dispersion of pallidofugal fibre systems. Rectangular pulses of 0·2 msec. duration, 100 pulses per sec., were obtained from a 'Tektronix 162' waveform generator and a 161 pulse generator which drove a cathode follower output stage. The output from the cathode follower was fed to the electrodes through a General Radio isolation transformer. Current was monitored on a 'Tektronix 502' oscilloscope for each pulse series. The current generally used was 2 m.amp.

As a result of these stimulations additional support was added to the theory of the dual nature of the

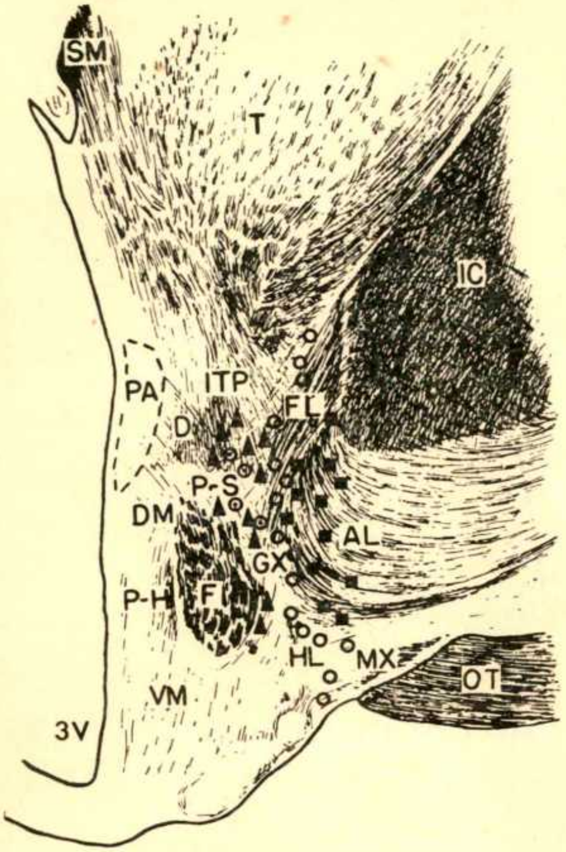

Fig. 1. Frontal section through the brain of the albino rat at anterior plane 5·8 of DeGroot with fibre systems indicated. organization of the 'feeding centre' and in the first part of the present work confirmation of Miller's[6] work has been obtained. In 8 animals electrical stimulation of the dorsal and lateral perifornical areas has resulted in selective feeding or drinking responses in satiated states. The areas stimulated to produce feeding and drinking behaviour are shown in Figs. 1 and 2, which represent the two sterotaxic frontal planes utilized. Both these figures show that feeding and drinking responses were obtained mostly from the dorsal and lateral perifornical areas and that these response areas were distinctly separated from other response areas in the far-lateral hypothalamic area by regions of no response. However, after lesioning the medial forebrain bundle anterior and posterior to the level of the 'feeding centre' and repeating these perifornical stimulations (same animals with electrodes in place) no feeding or drinking responses were obtained in any of the animals. On the other hand, it was previously shown[11] that sated animals stimulated in the far-lateral hypothalamic area would feed even with the medial forebrain bundle lesioned. These far-lateral stimulated animals would not, however, run an electrical barrier to press a lever for food. Before lesioning the medial forebrain bundle the animals stimulated in the far-lateral hypothalamic areas would both feed in the sated state and run the electrical barrier to press a lever for food. This evidence certainly indicates essential differences in behaviour produced by the mid-lateral (or perifornical) stimulation as opposed to far-lateral stimulation. Figs. 1 and 2 also indicate the areas in the far-lateral hypothalamus stimulated in the present experiments. Stimulations in the areas shown provoked feeding in sated animals regardless of whether or not the medial forebrain bundle was intact.

Also in the present experiments we compared Grossman's studies as to the effects of injecting adrenergic and cholinergic drugs into the dorsal and lateral perifornical areas with the effects seen after these same substances were injected into parts of the far-lateral hypothalamus. Selective feeding and drinking responses were obtained from the perifornical areas, the adrenergic substances producing feeding in the sated state and the cholinergic substances 'pure' drinking responses. In these animals (with injection needles in place), after section of the medial forebrain bundle anterior and posterior to the level of the 'feeding centre', no feeding or drinking responses could be evoked by injection of these drugs into the perifornical areas. In another group of animals injection of adrenergic and cholinergic drugs into the far-lateral hypothalamus produced somewhat different results. Adrenergic drugs did

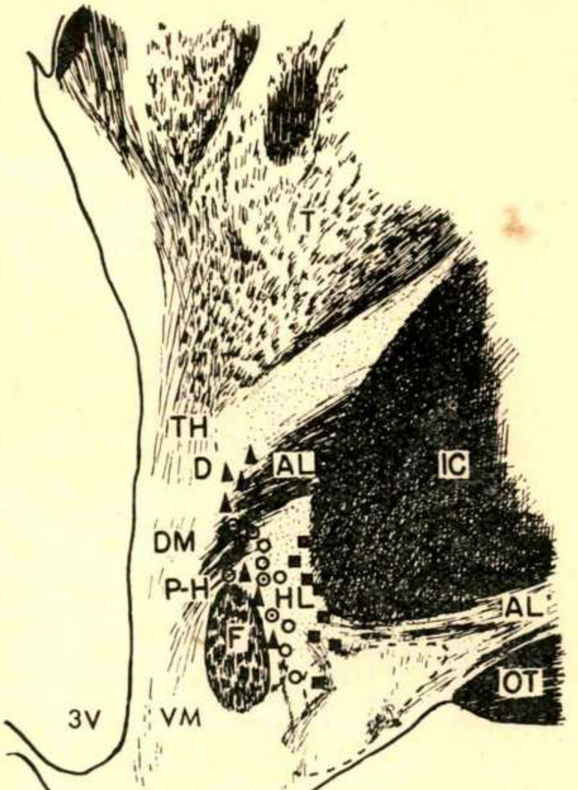

Fig. 2. Frontal section through the brain of the albino rat at anterior plane 4·9 with fibre systems indicated. Feeding and drinking responses designated as in Fig. 1. Notations for fibre systems and nuclei as in Fig. 1. *TH*, thalamo-hypothalamic fibres

provoke feeding in the sated state, but no 'pure' drinking responses could be obtained with cholinergic substances. After section of the medial forebrain bundle in this far-lateral group, however, feeding responses in the sated state were still easily obtainable following injection of adrenergic materials. These feeding responses were obtained from the same areas of the far-lateral hypothalamus as those that responded to electrical stimulation (Figs. 1 and 2). It is clearly seen from these figures that the critical areas are directly in the dispersion fields of the pallidofugal fibre systems (ansa lenticularis and lenticular fasciculus of Forel).

It is concluded that the mid-lateral and perifornical portions of the lateral hypothalamus contain 'hunger motivational' systems important in food drives. Intactness of the medial forebrain bundle seems necessary for this system to function properly since this system can only be activated (by stimulation or drug injection) in sated animals to produce further eating (or drinking) if the medial forebrain bundle is intact. Oddly enough, stimulation farther laterally in the far-lateral hypothalamus will cause sated animals to feed even when the medial forebrain bundle is lesioned; on the other hand, certain learned food-seeking responses are not provoked by far-lateral stimulation when the medial forebrain bundle is disjoined. It thus seems that the far-lateral mechanism is the more 'basic' feeding system and is mostly dependent on activation of pallidofugal fibre trajectories having primary influences perhaps on neuro-metabolic regulations. The medical and perifornical systems seem to be purely 'motivational' in nature, that is, are concerned only with the 'urge' of the animal to approach food and water.

EVIDENCE FOR A NEW ENZYME CONNECTED WITH PROTEIN SYNTHESIS

By HANS G. BOMAN and INGVAR SVENSSON

Institute of Biochemistry, University of Uppsala

THE enzymic reaction which incorporates amino-acids into soluble RNA has been so extensively studied that only review references can be given here[1-4]. The first step involves the formation of an enzyme-bound amino-acid adenylate compound. The second step is the transfer of the activated amino-acid to the 2′- or 3′-hydroxyl of the terminal adenosine residue in the soluble RNA. The overall reaction is summarized by the following formula:

$$\text{amino-acid}_1 + \text{adenosine triphosphate} + \text{soluble}$$
$$\text{RNA}_1 \overset{\text{enzyme}_1}{\rightleftarrows} (\text{amino-acid}_1)\text{-RNA}_1 + \text{adenosine}$$
$$\text{monophosphate} + \text{inorganic pyrophosphate} \quad (1)$$

Most probably there is at least one specific acceptor RNA molecule and one specific enzyme for each amino-acid, and the same enzyme ('the activating enzyme') should be able to carry out the activation and the transfer to the soluble RNA. Purifications of more than a dozen activating enzymes from various sources have been reported[1-4]; but so far most of these preparations have not been obtained in a pure and homogeneous form. It may also be significant that these enzymes show very low figures for turnover number when such calculations are possible for the overall reaction (1).

In this article we are recording a few experiments which may contribute additional information about reaction (1). We have prepared two partially purified enzymes: the arginine activating enzyme from *Escherichia coli*[5] and the methionine activating enzyme from yeast[6]. The methionine incorporating activity of these two enzymes in combination has been found to be up to twelve times as large as the sum of their separate activities. This finding, together with kinetic observations and metal ion effects, is taken as evidence for the existence of a new enzyme connected with reaction (1).

The RNA was prepared from bacteria by extraction of the whole cells with 90 per cent phenol followed by alcohol precipitation of the total RNA from the water phase. The soluble RNA was extracted from the precipitate by cold *M* sodium chloride[7] and further purified by precipitation with lanthanum nitrate[8]. The lanthanum salt of soluble RNA was dissolved in 0·5 *M* ethylenediamine tetraacetic acid of *p*H 4·7 and finally dialysed against distilled water for 15 hr. The activity of the activating enzymes was measured as the ability to incorporate C-14 amino-acids into soluble RNA. The assay volume was either 0·5 or 0·2 ml. and the reaction mixture contained varying amounts of soluble RNA and activating enzyme, 0·11 m*M* C-14 L-amino-acid, 2 m*M* adenosine triphosphate, 2 m*M* glutathione, 4 m*M* magnesium chloride and 0·1 *M* *tris*-maleate buffer, all adjusted to *p*H 7·0. The reaction was terminated by precipitation with 0·01 *M* lanthanum nitrate in 0·5 *M* perchloric acid. Carrier RNA was added, the precipitate was washed and the radioactivity determined with a windowless gas-flow counter as described in detail elsewhere[5].

During the study of the partially purified arginine activating enzyme, it was found to be gradually inactivated at 0° and *p*H 4·1. The time-dependence

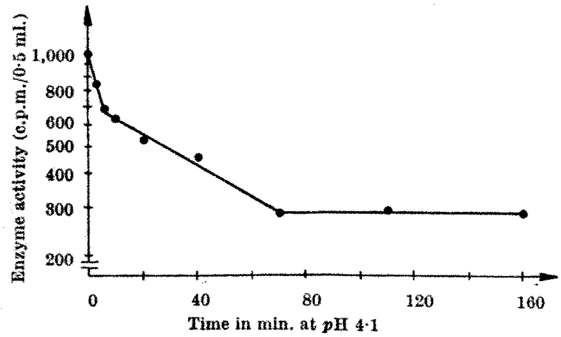

Fig. 1. Denaturation of arginine activating enzyme at 0° and *p*H 4·1. Enzyme activity measured as C-14 arginine–RNA formed in 15 min. at 37°. Assay volume 0·5 ml. with 4·3 μgm./ml. of enzyme and 4·0 mgm./ml. of soluble RNA. The activity is plotted on a logarithmic scale and is given in c.p.m. corrected for background and the mean blank, but not for self absorption

for this denaturation is shown in Fig. 1. The assay was performed with an enzyme concentration of 4·3 μgm./ml. and a soluble RNA content of 4 mgm./ml., conditions which make the enzyme rate-limiting for more than 15 min. Three blanks were used: one with enzyme heated to 70° for 10 min. gave 160 c.p.m., one with 0·02 *M* ethylenediamine tetraacetic acid *p*H 6·8 gave 150 c.p.m., and one with 0·002 *M* *p*-chloromercuribenzoate gave 165 c.p.m. The mean value of these blanks has been subtracted from the data given. Fig. 1 shows that about 25 per cent of the enzyme activity is stable at *p*H 4·1 and that the denaturation cannot be a single first-order reaction, but might be the sum of two such reactions. It has been checked that a partially denatured sample cannot be reactivated by standing at *p*H 7·0.

Berg and his associates[3] have compared the incorporation of methionine into *E. coli* soluble RNA when using methionine activating enzymes from the same source and from yeast. They found the bacterial enzyme to incorporate more than twice as much as the yeast enzyme. This result has been interpreted as a heterogeneity in the methionine accepting RNA[3,4]. We have used the working hypothesis that Berg's observation could be related to the results given in Fig. 1 and that such systems might permit the assay of different enzymes involved in the transferring of the same amino-acid to the soluble RNA. An attempt was thus made to purify the arginine activating enzyme from yeast (*Saccharomyces cerevisiae C*836) and it was found that the preparation *AS*-1 of the methionine activating enzyme described by Berg[6] was a potent source of enzyme for the incorporation of both arginine and methionine as seen from Table 1. It can also be seen that the two enzyme preparations have almost the same specific activity for the methionine incorporation, but that in combination they have about 13 times higher specific activity.

Table 1. RATE CONSTANTS AND SPECIFIC ACTIVITIES FOR THE ENZYME PREPARATIONS

Incorporation in soluble RNA with	C-14 L-arginine		C-14 L-methionine	
Enzyme preparation	Rate in c.p.m./min.	Spec. act.	Rate in c.p.m./min.	Spec. act.
Arginine activating enzyme from *E. coli*	72·2	20·2	1·0	0·014
Methionine activating enzyme from yeast	7·5	0·014	12·8	0·016
Methionine activating enzyme + arginine activating enzyme	94·4	—	167	0·210
Methionine activating enzyme + *p*H 4 treated arginine activating enzyme	—	—	25·6	0·027

The experiments with both enzymes in combination were performed with the same amount of the same enzyme preparations which were tested alone. The experiment in the last line was carried out with another preparation of methionine activating enzyme with a specific activity of 0·028. The rate constants are derived from the initial slopes of time-curves using 0·2 ml. assay volume. The specific activities are given in mμmoles of amino-acid incorporated at 27° (in an excess of soluble RNA) per min. and per mgm. of protein.

The effect of the combined enzyme preparations has been further examined in kinetic experiments of various types. Fig. 2 shows two parallel experiments when arginine activating enzyme was added to a reaction with methionine activating enzyme. The result is a significant increase in the formation of methionine–RNA, while the control experiment with arginine activating enzyme shows only a minor incorporation. The addition of more methionine activating enzyme after 60 min. does also give an increased formation of methionine–RNA indicating that soluble RNA does not become rate-limiting during the experiment. One of the experiments in Fig. 2 was carried out with C-14-methyl labelled L-methionine (represented by circles) the other with C-14-(C2) labelled DL-methionine (represented by squares); both obtained from California Corporation for Biochemical

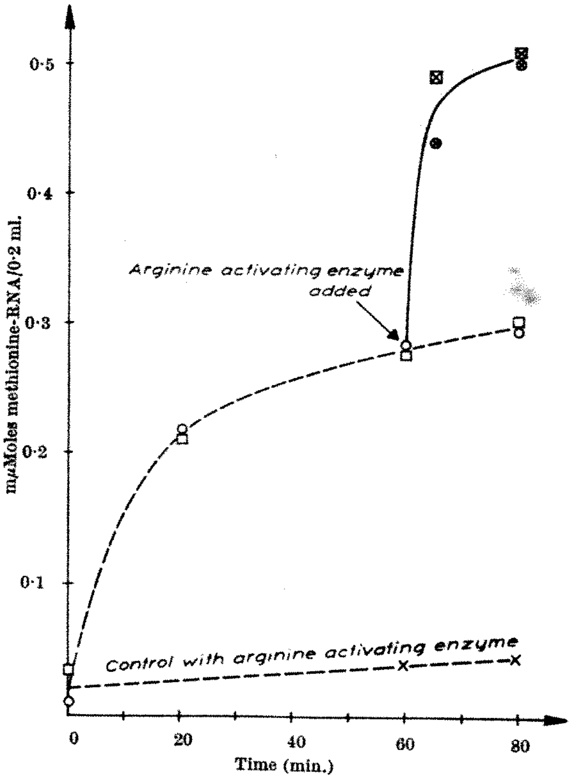

Fig. 2. Two parallel kinetic experiments at 27° with 1·24 mgm./ml. of methionine activating enzyme and 3·1 mgm./ml. of soluble RNA. Arginine activating enzyme (final conc. 0·17 mgm./ml.) was added to the reaction mixture after 60 min. Aliquots of 0·2 ml. were withdrawn at various times and assayed for C-14 methionine-RNA. Circles represent L-methionine with methyl-C-14, squares DL-methionine with (C2)-C-14. The crosses represent an experiment with 0·098 mgm./ml. of arginine activating enzyme, 2·6 mgm./ml. of soluble RNA and L-methionine with methyl-C-14

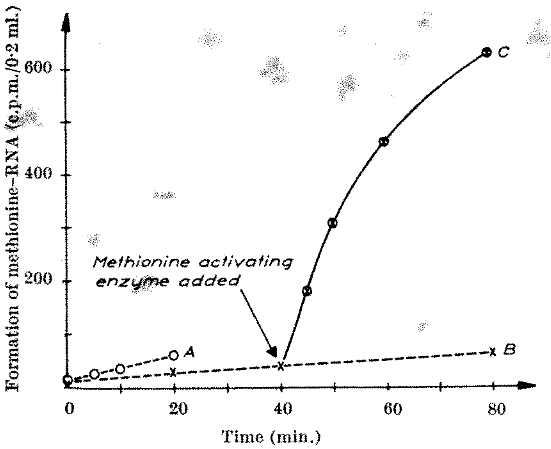

Fig. 3. Kinetic experiment at 27° showing the formation of methionine–RNA using 0·75 mgm./ml. of methionine activating enzyme (curve *A*) and using 68 μgm./ml. of arginine activating enzyme (curve *B*). After 40 min. was added to the latter reaction mixture methionine activating enzyme to a final concentration of 0·75 mgm./ml. (curve *C*). The concentration of soluble RNA was 4·5 mgm./ml. for curves *A* and *B*, 4·1 mgm./ml. for curve *C*. Assay volume 0·2 ml. The activity is given in c.p.m. and corrected only for background

Research, Los Angeles, 63. The agreement between the two experiments rules out a transmethylation reaction.

Both the enzyme preparations were stored at – 18° C. with 50 per cent ethylene glycol as antifreeze. In these conditions, the arginine activating enzyme has been stable for 7 months, while the methionine activating enzyme gradually has become less active. Fig. 3 shows the time-curves for the formation of methionine–RNA using a somewhat inactivated preparation of methionine activating enzyme (curve *A*) and a normal preparation of arginine activating enzyme (curve *B*). After 40 min. the same amount of the same preparation of methionine activating enzyme was added to the latter reaction mixture as was used for curve *A*. The suddenly increased formation of methionine–RNA obtained by the combined enzymes (curve *C*) corresponds to about a nine-fold increase in specific activity.

Most enzymic reactions are characterized by the fact that the enzyme concentration is rate-limiting in the beginning, while the substrate concentration becomes limiting towards the end of the reaction. Curves corresponding to this type of kinetics are also found for the formation of arginine–RNA using the arginine activating enzyme and for the formation of methionine–RNA using both the arginine and the methionine activating enzymes together. However, the curve obtained with the methionine activating enzyme alone is approximately logarithmic with time (as in Fig. 2) and similar curves are obtained also with arginine activating enzyme which has been kept at 0° and *p*H 4·1 for 80 min. Such logarithmic curves may be expected when a rate-limiting component is disappearing in a first-order reaction.

Some factors which could be expected to influence the rate or the equilibrium position of reaction (1) have been tested for their possible effects. Both the enzyme fractions have been pre-incubated at 27° for 80 min. without any detectable change of activity. The addition of crystalline pyrophosphatase[10] and purified venom 5′-nucleotidase[11] had no influence on the course of the reaction. An instability of one of the enzyme fractions or a trapping of the reaction products can thus be eliminated as interpretations.

However, it was found that in the presence of magnesium, the addition of calcium, cobalt or manganese ions has a pronounced stimulating effect on the methionine activating enzyme preparation, but a slight inhibitory action on the preparation of arginine activating enzyme. On the other hand, the addition of ashed preparations of the respective enzymes had scarcely any effect on the reaction. Thus the sudden increase in the formation of methionine–RNA observed with both enzymes together (Figs. 2 and 3) cannot be a metal-ion effect.

All the results reported here could be explained by the following hypothesis, which is based on two assumptions. (*a*) The activating enzyme is consumed during the course of the reaction (1). It could be that the reaction produces a chemical change in the enzyme or that 'the enzyme-substrate compound' formed is not split into 'product and enzyme'. The methods used do not distinguish between these alternatives, but both may be expected to give logarithmic time-dependences. (*b*) A second enzyme exists which is capable of regenerating the methionine, as well as the arginine activating enzyme. This 'regenerating enzyme' is present in an excess in the arginine activating enzyme preparation, which cannot be regarded as highly purified despite its high specific activity (see Table 1). The methionine activating enzyme was purified about fifty-fold[6], but has probably been freed of the 'regenerating enzyme', which explains both its relatively low specific activity and the stimulation by the arginine activating enzyme (Table 1).

The 'regenerating enzyme' may have its maximum activity with magnesium ions, which explains the general agreement[1–4] about the requirement for this metal ion. We have determined that the arginine activating enzyme has its maximum activity with 0·01 *M* magnesium but that about 50 per cent activity is obtained with manganese. The alanine activating enzyme from pig liver cytoplasm requires cobalt[12], and the tyrosine activating enzyme from rat liver has recently been shown to require potassium[13]. Other activating enzymes may show optimum activity with other metal ions such as calcium, iron and manganese, all of which are known to be present in RNA preparations[14], but which are removed by our treatment with ethylenediamine tetraacetic acid. Preliminary experiments have indicated that besides methionine this would be the case with the enzyme for phenylalanine.

The difference between the methionine activating enzymes from yeast and from bacteria observed by Berg *et al.*[9] can thus be explained by assuming that their preparation of the bacterial enzyme contains the 'regenerating enzyme' and that this is absent in the preparation of the yeast enzyme. Zillig *et al.*[15] have reported that the amount of leucyl–RNA which can be formed by their '*p*H 4 enzyme' is directly proportional to the amount of enzyme used, and suggest that the normal reaction product is a complex of amino acyl soluble RNA and enzyme. Our interpretation would be that the 'regenerating enzyme' is denatured by the *p*H 4·5 precipitation used by these authors, as well as in our *p*H 4·1 experiments with the arginine activating enzyme (Fig. 1 and Table 1). Such a denaturation would explain why enzyme preparations subject to the acid treatment show the anomalous dependence on enzyme observed.

In conclusion, we feel that our results are in agreement with the previous findings of Berg's and Zillig's groups, and that together with our own data they support the hypothesis of the existence of a 'regenerating enzyme' coupled to the activating enzymes which catalyse reaction (1). Such a coupling could be a powerful control mechanism, but speculations about its possible function *in vivo* may await further experimental data. It is a consequence of our hypothesis that in the presence of soluble RNA reliable measurements with activating enzymes cannot be performed without an excess of 'regenerating enzyme'.

This work has been supported by Grant No. *RG*–7576 from the U.S. Public Health Service.

Note added in proof. Dr. Paul Berg has kindly informed us that soluble RNA from bacteria can be obtained in a form in which a fraction of the chains lacks the adenosine end-group. Consequently the effect of the arginine activating enzyme preparation could be due to incorporation of adenosine monophosphate, which would increase the number of acceptor sites for methionine. However, preincubation of our soluble RNA with the arginine-activating enzyme preparation and adenosine triphosphate has failed to demonstrate any increase in the number of acceptor sites for methionine.

PHOTOPHOSPHORYLATION AND THE HILL REACTION

THE rate of the Hill reaction has been reported to be stimulated strongly by concomitant photophosphorylation, that is, by synthesis of adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and orthophosphate[1–4]. Warburg *et al.*[5] have pointed out that this stimulation of the rate of photoreduction is an effect of *p*H, but the warning appears to have gone unheeded. Most recently, for example, Good[6] has used such a stimulation to distinguish between phosphorylating and non-phosphorylating electron transport; he suggests that the latter should be subtracted from the former to obtain the true ratio of micromoles ATP formed to electron pairs transferred (P/2*e* ratio), and concludes that this value is 2. Good cites a similar value of 2 reported by Krogmann and Vennesland[7] for the stoichiometry of oxidative photophosphorylation. We must point out, however, that the assumptions underlying the latter calculation are quite different from those made by Good, and may or may not be correct. At the same time, our own work on the dependence on *p*H of the Hill reaction leads us to the conclusion that Warburg is correct in attributing rate stimulation by associated phosphorylation to effects of *p*H.

Punnett[8] has noted that freshly prepared chloroplasts photoreduce ferricyanide most rapidly at a rather alkaline *p*H. With spinach chloroplasts freshly prepared in 0·35 *M* sodium chloride, the *p*H optimum we observe is generally greater than *p*H 8. The rates at the maximum, in saturating light, range up to 600 μmoles per mgm. chlorophyll per hr. at 15° C., and may be as much as four times faster than the rates measured at *p*H 7 with the same chloroplast preparations. Fig. 1 shows the dependence on *p*H of photoreduction and photophosphorylation in 0·05 *M* *tris*(hydroxymethyl)aminomethane buffer, where the abscissa represents the initial *p*H of the reagents employed. Reactions were carried out in 25-ml. conical flasks incubated at 15° C. with air as the gas phase. Each vessel contained in micromoles: *tris*(hydroxymethyl)aminomethane, 100; potassium ferricyanide, 10; magnesium chloride, 10; and, where indicated, potassium phosphate and adenosine diphosphate, 3·4 in a final volume of 2·0 ml. *Tris*, phosphate, and adenosine diphosphate solutions were adjusted to the indicated *p*H with the use of hydrochloric acid and sodium hydroxide and a Leeds and Northrup *p*H meter. Chloroplasts, freshly prepared in 0·35 *M* sodium chloride and used without prior washing, containing 113 μgm. of chlorophyll were added to the vessels at zero time. The reactions were initiated and terminated by turning the light on and off; illumination was from below for 4 min., with shaking, and with white light of about 5,000 ft.-candles. Reaction mixtures were deproteinized by adding 0·50 ml. of 20 per cent (w/v) trichloracetic acid and centrifuging. Residual ferricyanide was determined on an aliquot of the supernatant by direct reading at 400 mμ in the Beckman *B* spectrophotometer. Residual orthophosphate was determined on a separate aliquot by the method of Fiske and Subbarow[9]; the reduced phosphomolybdate complex was read in a Lumetron colorimeter with a 650-mμ filter, after centrifuging to remove the precipitate of ferrocyanide–molybdate. Chlorophyll was determined by Arnon's method[10].

The upper curves represent ferricyanide photoreduction in the presence of ADP and orthophosphate (solid circles) and in the absence of both ADP and orthophosphate (open circles). The largest effect of these reagents (20 per cent stimulation) is seen at the lowest *p*H. This effect diminishes as the initial *p*H approaches the *pK* of the buffer (8·2), and it could be enhanced by the use of lower buffer concentrations. This behaviour can be accounted for on the basis of the formation of hydrogen ions during ferricyanide photoreduction (equation 1) and the consumption of hydrogen ions during the synthesis of ATP (equation 2):

$$2\mathrm{Fe(CN)}_6^{3-} + \mathrm{H_2O} \rightarrow 2\mathrm{H}^+ + 2\mathrm{Fe(CN)}_6^{4-} + \tfrac{1}{2}\mathrm{O}_2 \qquad (1)$$

$$\mathrm{ADP}^{3-} + \mathrm{HPO}_4^{2-} + \mathrm{H}^+ \rightarrow \mathrm{ATP}^{4-} + \mathrm{H_2O} \qquad (2)$$

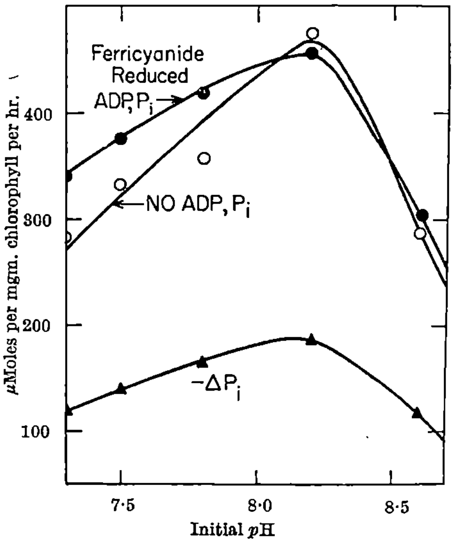

Fig. 1. Dependence on *p*H of ferricyanide photoreduction and phosphate uptake by spinach chloroplasts in the presence and absence of a phosphorylation system

The lower curve of Fig. 1 shows the rate of phosphate consumption accompanying ferricyanide photoreduction in the presence of ADP and phosphate. It should be noted that the rate of phosphorylation here is proportional to the rate of ferricyanide reduction and that the P/2*e* ratio is about 0·8 throughout the *p*H range. If we were to apply the correction suggested by Good[6] for non-phosphorylating electron transport in the calculation of the P/2*e* ratio, values for the latter in this experiment would range from four to infinity.

The reaction conditions detailed in Fig. 1 have been employed extensively in our laboratory for the study of the stoichiometry of the Hill reaction and associated photophosphorylation. An examination of published results from other laboratories[4] shows that very large stimulations of ferricyanide photoreduction by ADP have been obtained with rather different reaction mixtures which contain ATP, higher concentrations of phosphate and lower concentrations of chlorophyll and ferricyanide, assayed with shorter illumination periods. Table 1 shows that we can also obtain a stimulation of the Hill reaction-rate under these conditions, even in well-buffered systems. The correct interpretation of the nucleotide effects shown in Table 1 is not entirely clear, and would seem to require further investigation. But from numerous experiments such as that illustrated in Fig. 1, it is clear that the addition of ADP and orthophosphate to adequately buffered chloroplast suspensions can elicit a good rate of photophosphorylation without appreciable stimulation of the rate of ferricyanide photoreduction. Thus we are in agreement with Warburg's conclusion, namely, that photophosphorylation can occur as a result of the Hill reaction, but that the rate of the latter is independent of the ATP synthesis which may or may not accompany it.

Table 1. EFFECT OF ADP AND ATP ON FERRICYANIDE PHOTOREDUCTION BY SPINACH CHLOROPLASTS

The reaction mixture contained in μmoles: *tris*(hydroxymethyl)-aminomethane, 82; potassium phosphate, 68; potassium ferricyanide, 2; magnesium chloride, 10; sodium chloride, 70; in a final volume of 3·0 ml., at *p*H 7·8, and chloroplasts containing 74 μgm. chlorophyll. Illumination was for 2 min.; other conditions and assay as described for the experiment in Fig. 1

Additions	Ferricyanide photoreduction (μmoles per mgm. chlorophyll per hr.)
None	282
1 μmole ADP	425
0·5 μmole ATP	172
1 μmole ADP + 0·5 μmole ATP	403

THE following considerations compel me to reject the *p*H theory:

(1) There is always much less formation of hydrogen ion associated with the reduction of flavins than with the reduction of ferricyanide. When flavins function catalytically in the reduction of oxygen, as in my usual test system, there is no hydrogen ion formation at all. Nevertheless, I find that the reduction of flavin mononucleotide is stimulated to the same extent as the reduction of ferricyanide by the presence of the phosphorylating system.

(2) The acid consumed in the phosphorylation of adenosine diphosphate reappears when the resulting adenosine triphosphate is used in the synthesis of glucose-6-phosphate. Yet the stimulation of ferricyanide and flavin reduction which is associated with the phosphorylation is independent of the presence or absence of hexokinase and glucose.

(3) Chloroplasts stored below *p*H 7·0 rapidly lose all ability to respond to the components of the phosphorylating system. These aged chloroplasts continue for a long time to reduce ferricyanide in the absence of the phosphorylating system at the same rate as freshly prepared chloroplasts. Consequently, the phosphorylating and non-phosphorylating electron transport systems must differ in at least one labile reaction step. This fact precludes the possibility that the rate-stimulation observed during phosphorylation represents the effect of improved conditions, *p*H or other, on a single process.

(4) The evidence presented by Stiller and Vennesland in support of Warburg's *p*H hypothesis contradicts the experience of most workers. I have carefully considered buffering problems and have established satisfactory buffer-levels by exhaustive experimentation without encountering phenomena of the kind described by the Chicago group. I believe that the high rates they attribute to "adequate buffering" are, in fact, an expression of the hitherto unrecognized uncoupling effect of high concentrations of salts. This effect of salts on chloroplasts will be documented in detail elsewhere. Chloroplasts I have

used exhibit the familiar pattern of behaviour regardless of the alkalinity and the concentration of the buffer when they are suspended in media low in ions; the complete phosphorylating system always causes large increases in the rate of ferricyanide reduction and there is always a quantitative relationship between the increase of rate and the amount of adenosine triphosphate formed. On the other hand, these same chloroplasts in 0·35 *M* sodium chloride are similar to, but not identical with, the Stiller–Vennesland chloroplasts. The condition described by Stiller and Vennesland, phosphorylation without stimulation, would be kinetically reasonable if their chloroplasts were both partially uncoupled and partially inhibited (as mine seem to be in 0·35 *M* sodium chloride). Thus the uncoupling might be sufficient to allow rates to rise to the maximum of a partially inhibited process which would then become rate-limiting. Yet this amount of uncoupling might still permit considerable phosphorylation; hence there is phosphorylation but no increase in the rate of electron transfer. However, the effects of salts on chloroplasts are very complex, with many as yet unexplored ionic interactions. Consequently there is little point in attempting a detailed interpretation of the Stiller–Vennesland observations at present.

Stiller and Vennesland (first communication) present a timely warning with respect to the interpretation of experiments measuring the rate of the Hill reaction when ferricyanide or other redox dyes are reduced. I agree that the *p*H of the reaction mixture can fall during the course of the reaction if insufficient buffer is present; and further that a concomitant phosphorylation of ADP will prevent this fall. My measurements also show a fairly sharp optimum at about *p*H 8; thus a downward drift in *p*H would cause a lower rate of dye reduction or of oxygen evolution.

It is another question, however, whether or not this sort of artefact is actually responsible for previously reported phenomena[1-3]; and whether in the complete absence of a drift of *p*H the rate of the Hill reaction is stimulated due to an accompanying phosphorylation reaction.

In our first account of stimulation of rate by adding ADP, magnesium and orthophosphate[1], which confirmed the earlier observation of Arnon *et al.*[4]; and also in our published work since then[2,3], the reactions were run at room temperature, in 3 ml. total volume containing either 0·030 or 0·040 mgm. of chlorophyll, 40 μmoles of *tris* buffer at *p*H 8, 70 μmoles of sodium chloride and 1·5 μmoles of ferricyanide. (Unfortunately the original tables (ref. 1) omitted mention of the *tris*; its presence was indicated only indirectly by reference to earlier papers.) The illumination period was 2 min., so that initial rates only have been measured. The control reactions, to which no other reagents were added, reduced at most one-third of the ferricyanide present, or 0·5 μmole. It seems quite unlikely that the equivalent amount of hydrogen ions generated could have lowered the *p*H significantly in the presence of 40 μmoles of *tris* at *p*H 8. A re-check of the same reaction conditions shows at most a *p*H fall of 0·1 unit in the control reactions. This could not be enough to account for more than a minor share of the difference in rate between the phosphorylating and non-phosphorylating reactions.

I have re-examined the rate of ferricyanide reduction as a function of *p*H, using 150 μmoles of *tris* buffer in 3 ml. volume as suggested by Stiller and Vennesland, in order to eliminate any possible drift of *p*H. The *p*H's of the reaction mixtures were all measured after illumination ended as a further precaution against undetected drifting. The results shown in Fig. 1 are from a typical experiment out of five repetitions. All points represent the average of duplicate samples, containing, in 3 ml. total volume, 0·040 mgm. of chlorophyll, 70 μmoles of sodium chloride, 150 μmoles of *tris* at an appropriate *p*H and 1·5 μmoles of potassium ferricyanide. Where indicated to be present, there were 30 μmoles of phosphate adjusted to the same *p*H as that of the *tris*, 10 μmoles of magnesium chloride, 0·2 μmole of ATP or 1·5 μmoles of ADP. The reaction mixtures were illuminated in small test-tubes for 2 min. at room temperature, at 5,000 ft.-candles (the source was an incandescent lamp with 5 cm. of water filter between the lamp and the reactions). The *p*H's shown were those of the reaction mixtures, determined on each sample after the reaction was ended. Following this, the mixtures were killed by adding 0·3 ml. of 20 per cent trichloracetic acid, the proteins removed by centrifugation, and optical density of the supernatant solution measured at 420 mμ in a Beckman spectrophotometer. The ferricyanide reduced was measured as the change in optical density from that of zero-time control, and no appreciable change could be seen without illumination. The chloroplasts were prepared by grinding spinach leaves in a buffer containing 0·40 *M* sucrose, 0·02 *M* *tris* buffer and 0·01 *M* sodium chloride at *p*H 8·0. They were centrifuged once, resuspended in 0·40 *M* sucrose/0·03 *M* sodium chloride, and used without washing. The entire *p*H series was accomplished within an hour and a half after grinding the leaves, the higher *p*H's being measured first.

The results show that reactions with and without a simultaneous phosphorylation have a similar response to *p*H; but at any one *p*H the rate is usually doubled owing to addition of ADP. As before[1],

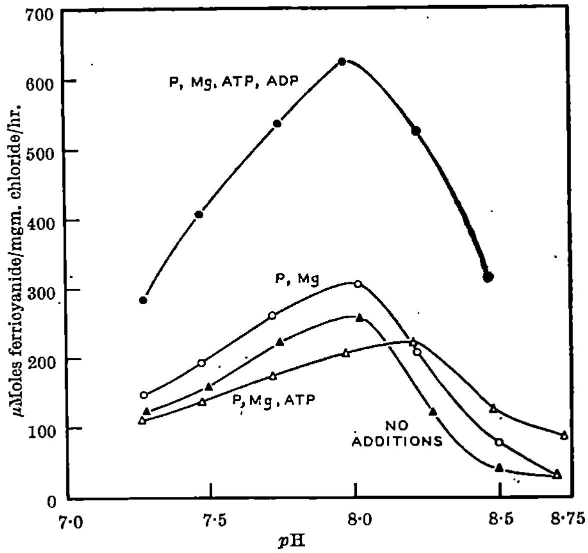

Fig. 1. Ferricyanide reduction by the Hill reaction as a function of *p*H of the reaction mixture

ATP at low concentrations has an inhibitory effect, so that if ATP, magnesium ions and orthophosphate serve as a control, the rate may be tripled owing to addition of ADP. These results correspond to those of Table 1 in the communication by Stiller and Vennesland. Although I agree that the interpretation of these results is not clear if they stand alone, we have previously[1] presented results from various other types of experiments, all of which supported the concept that the actual process of simultaneous phosphorylation was responsible for the observed increase of rate.

It was recently discovered that the rate of reduction of triphosphopyridine nucleotide (TPN) is stimulated by adding all three reagents required for phosphorylation (ref. 5, and San Pietro and Keister, in preparation). Although the extent of such stimulation may be four-fold, or even more, a *p*H drift of no more than 0·03 unit can be seen under the reaction conditions used (San Pietro and Keister, personal communication). Furthermore, the *p*H response for reduction of TPN appears to be considerably less steep than that for ferricyanide reduction.

In view of all these results, I must take exception to the generalization implicit in the statement of Stiller and Vennesland attributing "... rate stimulation by associated phosphorylation to effects of *p*H". The statement obviously cannot apply to the results obtained under the conditions of my Fig. 1, or of Table 1 of Stiller and Vennesland. This interpretation of stimulation of rate has a chance of being significant only when the Hill reaction is allowed to proceed for longer periods of time, generating major amounts of hydrogen ions (as is usual when manometric procedures are used, for example). It should be noticed that in Fig. 1 of Stiller and Vennesland the 4-min. reaction period with a fairly high chlorophyll-level leads to the generation of approximately 4 μmoles of hydrogen ions, rather than the 0·5 μmole or less under my conditions.

It is always possible that under differing conditions a particular phenomenon may not appear. Using the reaction conditions as described by Stiller and Vennesland for their Fig. 1, I have confirmed their observation that the Hill reaction-rate is unchanged (or shows no more than a 5–10 per cent stimulation) due to a simultaneous phosphorylation. I have found that one condition contributing significantly to the smaller effect is the low concentration of phosphate employed ($1{\cdot}67 \times 10^{-3}$ *M*) compared with that needed for a maximal rate of phosphorylation[1,6]. It seems to me reasonable that in a complex system with a very significant basal level at all times, close to optimal conditions will be required for the induced reactions to become apparent. The possible role of other factors in diminishing the rate-stimulation by ADP, magnesium ions and orthophosphate is at present under investigation.

As Stiller and Vennesland point out, the variations possible in relative rates between phosphorylating and non-phosphorylating reactions make the calculation of the P/2*e* ratio after subtracting the basal rate an extremely questionable operation. It seems to me that this same demonstrable variation also invalidates the generalization implicit in the statement of Stiller and Vennesland, "... that photophosphorylation can occur as a result of the Hill reaction, but that the rate of the latter is independent of ATP synthesis which may or may not accompany it".

BIOLOGY OF REPRODUCTION IN *RUBUS*

By Dr. G. J. DOWRICK

Department of Biological Sciences, Wye College, nr. Ashford, Kent

APOMIXIS has, in the past, been frequently defined to include diverse types of vegetative reproduction such as bulbil formation and vegetative proliferation[1]. In this account the use of the term is restricted to embryo formation from a cell which has not undergone meiosis and has not been fertilized. It is usually assumed that many polyploid species of *Rubus* reproduce either by facultative or obligate apomixis. Thus *R. laciniatus* ($2n = 4x = 28$) is believed to be an example of a facultative apomict while *R. caesius* ($2n = 28$) is reported as being entirely apomictic. In *Rubus*, unreduced egg cells have been considered to be aposporic in origin, and it was assumed that embryos develop without fertilization. Development of embryos is, however, dependent on pollination which, presumably, is necessary for fertilization of the endosperm (unreduced pseudogamy). The results presented here show that the breeding behaviour of tetraploid *Rubus* species does not follow this accepted pattern, but that embryos develop from haploid embryo-sacs arising by a normal meiotic sequence from megaspore mother cells.

Three tetraploid species, *R. caesius*, *calvatus* and *laciniatus*, have been investigated and in all three species meiosis was normal and embryo-sac formation followed the *Polygonum* type of development. Development has been studied in particular detail in *R. caesius* since this species has been stated to be an obligate apomict[2]. All stages of meiosis have been found in the megaspore mother cell and at MI there were 14 bivalents. Subsequent chromosome separation was normal and a young tetrad was seen regularly. All stages in the development of the embryo-sac have been observed with the exception of the third embryo-sac division. There was no evidence of

* × *R. ulmifolius*; † × *R. tomentosus*.

restitution and embryo-sacs, where counts could be made, had a haploid chromosome number. Thus there was no evidence of apospory.

Chromosome numbers of progeny from crosses between these three tetraploid species and other species of different ploidy have been determined. As an example of the variation found in chromosome numbers counts from crosses involving *R. laciniatus* are shown in Table 1. It will be seen that 62·3 per cent of the seedlings had the same chromosome number as the maternal species. The phenotypic appearance of these plants made it clear that they were identical to *R. laciniatus*. However, from the embryological evidence it is now known that they cannot be apomictic, since no unreduced embryo-sacs were formed.

In addition to these maternal-like seedlings there were both reduced and unreduced sexual seedlings, as shown by the plants having 21 and 35 chromosomes in families derived from diploid male parents. The former are considered to have been derived from fertilized reduced egg cells; the latter from reduced egg cells which, before fertilization, have become diploidized in the way described here. Plants with 21 chromosomes could be distinguished readily from those with 35 on phenotypic characters. The *laciniatus* leaf character is phenotypically recessive in the triploid and relatively more dominant in the pentaploid, where the proportion of *laciniatus* chromosomes is higher. The high frequency of plants with 35 chromosomes was unexpected and this class has not been reported previously. Relatively few seedlings with chromosome numbers different from *R. laciniatus* were formed in families derived from parents of higher ploidy. The two haploid seedlings with 14 chromosomes form a fourth class of progeny. These were derived directly from reduced egg cells. In addition, there were four aneuploids in the 91 seedlings examined.

The origins of two classes of progeny, the triploid sexuals and haploids, present no difficulty since the former are simply the products of reduced, fertilized egg cells while the latter have been developed from reduced unfertilized egg cells. Both classes have been reported previously and will not be considered further.

Since all megaspore mother cells in this material were seen to undergo meiosis, the production of tetraploid maternal-like and of pentaploid sexual progeny requires more careful consideration.

The former could arise in one of two ways: either restitution at the first division of the egg cell or 'fusion' of the nuclei within the embryo-sac, that is, automixis, must occur. Evidence of diploid parthenogenesis is found in *Petunia nyctaginiflora*[3]. This species, when pollinated with either *Salpiglossis variabilis* or *Nicotiana tabacum*, produces only homozygous *Petunia nyctaginiflora* seedlings. These are formed as a result of diploidization by restitution in the egg cell. Previous workers have suggested that automixis was a reproductive mechanism found in *Rubus*, although it has usually been considered to be of little general significance[4,5]. In the present material it was impossible to establish the method whereby doubling of haploid nuclei in the embryo-sac occurred. Since the genetic consequences of the two possible methods suggested above are the same, the critical establishment of the method of doubling is of minor significance.

Pentaploid sexual progeny must arise from egg cells which have undergone meiosis, become diploidized and later fertilized.

A further class of progeny which has been termed *sub-sexual* has been described by previous workers[6,7]. Phenotypically these are plants similar to the maternal species, have the same chromosome number, but are not genetically identical to it. Sub-sexual progeny are assumed to arise from diplosporic egg cells, which are themselves derived from megaspore mother cells in which a normal meiotic prophase is followed by restitution. Such egg cells have undergone genetic crossing over, but retain the somatic chromosome number. There is no cytological evidence for the occurrence of such a process in the tetraploid *Rubus* species studied.

One of the genetical implications of the reproductive mechanism now put forward is that the tetraploid species concerned are homozygous. However, since they are almost certainly amphi-diploids, as shown by their cytological behaviour during meiosis, there will be homozygosity only between the chromosomes of each of the two complexes which together make up the tetraploid. They will be heterozygous as a result of differences between the two complexes. Crossing-over, though it occurs, will not result in segregation, and diploidization either in the egg cell or as a result of automixis will immediately restore the full chromosome complement of the female parents. The sub-sexual plants might then arise from occasional allosyndetic pairing and crossing-over between the chromosomes of the two different complexes.

It has been shown before that the proportion of sexual progeny produced by a supposed apomict may differ with different pollinating parents. Further, it has been shown that species which in particular circumstances are sexual are, in different circumstances, also apomictic[8]. Thus *R. vitifolius*, when pollinated with diploid *R. idaeus*, gives only sexual progeny, whereas the same species when pollinated with the tetraploid form of *R. idaeus* gives both sexual and 'apomictic' seedlings. The breeding of this species is most easily explained on the basis that only one type of embryo-sac is formed, that is, sexual, and the subsequent development varies according to the pollinating parent used. If both sexual and apomictic seedlings were produced, it is difficult to understand why, in the cross involving diploid *R. idaeus*, apomictic progeny are not produced. These results also suggest that diploidization occurs at the first division of the egg, rather than as a result of automixis since, if the latter mechanism occurred, maternal-like seedlings would be expected from the cross using diploid *R. idaeus*.

Much of the evidence for apomixis in *Rubus* has been derived from chromosome counts[9]. The chromosome counts of apomictic seedlings will be identical to those of the maternal species from which they arose. Many of the counts cited involve self and open pollinations. Since sexual seedlings derived from such crosses may also retain the maternal chromosome number, they are, however, inadmissible. Nevertheless, pollinations between parents of widely different ploidy do frequently produce a high proportion of maternal-like seedlings. In crosses between tetraploid female parents and various male parents, Einset found that the number of reduced parthenogenetic seedlings (43) was almost as great as the total number of sexual seedlings (46) and higher than might be expected when compared with the number of supposed apomictic tetraploids (592). These relative frequencies suggest that reduced embryo-sacs are of much greater significance than hitherto realized.

Two other recent accounts of reproductive mechanisms in *Rubus* are relevant to the present work. Christen found evidence in *R. caesius* that only sexual embryo-sacs are formed[10]. Similarly, Markarian and Olmo suggested that there was no evidence for the formation of aposporic embryo-sacs in another 'apomict', *R. procurus*[11]. It was assumed by these workers that the form of the species studied must have been atypical of the species generally, or that the aposporic stages of embryo-sac formation had been missed. Neither of these possibilities is true of the present work. Clones of *R. caesius* from England, Finland and Poland have now been examined and in all only reduced sexual egg cells were formed. Also, the frequency with which the sexual stages of development were seen makes it impossible to consider that the development of aposporic embryo-sacs has been overlooked.

The high proportion of seedlings with 35 chromosomes, which, as shown here, were derived from pollination of *R. laciniatus* with diploid male species gives still further evidence against an apomictic mechanism. Fertilization of aposporic egg cells would be unlikely to occur if apomixis, as is generally supposed, enables a species, which would become extinct under a sexual system, to reproduce itself.

The evidence not only from this study but also from previous work suggests, therefore, that apomixis in its commonly accepted sense, is not an important reproductive mechanism in tetraploid forms of *Rubus*. The production of maternal-like progeny, though superficially simulating apomixis, depends solely on the formation of reduced egg cells.

Much of this work was carried out at the John Innes Institute, and I am particularly grateful for the stimulating guidance of Mr. Watkin Williams and for the technical assistance of Miss P. Dow.

SOME CHARACTERISTICS OF MITOCHONDRIA EXTRACTED FROM HIGHER PLANTS

By Dr. WALTER D. BONNER, Jun., and DINOR O. VOSS

Eldridge Reeves Johnson Foundation for Medical Physics, University of Pennsylvania, Philadelphia

With the exception of one brief note[1] there are no instances in the literature showing control of respiratory activity in mitochondria isolated from higher plants. The purpose of this article is to show some of the characteristics of higher plant mitochondria that do possess such respiratory control.

There are instances on record (cf. ref. 2) which show a modest increase in plant mitochondrial oxidative activity (up to twice) in the presence of adenosine diphosphate. It is possible to obtain mitochondria which show no utilization of oxygen following addition of substrate (succinate) but which are maximally active following addition of a minute amount of adenosine diphosphate. The increase in rate of utilization of oxygen following addition of adenosine diphosphate is usually about ten times. In such instances (Fig. 1) the utilization of oxygen does not decrease on exhaustion of adenosine diphosphate, and there is a curious induction period following its addition before steady-state conditions are achieved. The induction period may well be related to the requirement for adenosine triphosphate for succinate oxidation (see discussion in ref. 3). The dependence of this type of plant mitochondria on adenosine diphosphate and the lack of control is not due to activity of mitochondrial adenosine triphosphatase but rather to several factors which sediment with starch and the mitochondria. The preparation of plant mitochondria that show oxidations controlled

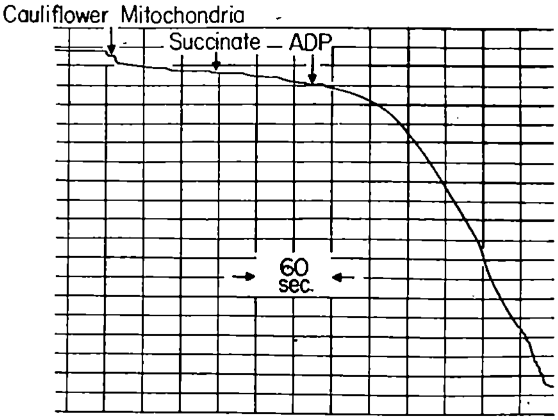

Fig. 1. Polarograph trace of the oxygen utilization by cauliflower mitochondria. Mitochondria suspended in a phosphorylating medium which consisted of: mannitol, 0·3 *M*; potassium chloride, 0·01 *M*; magnesium chloride, 0·005 *M*; potassium dihydrogen phosphate, 0·01 *M*; versene, 10^{-4} *M*; *p*H 7·4. Succinate = 0·005 *M*; the concentration of adenosine diphosphate resulting from each addition was 125 *μM*

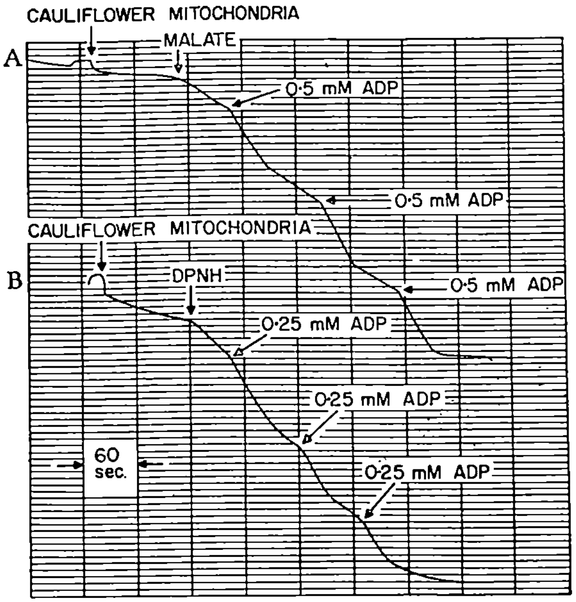

Fig. 2. Polarograph traces of oxygen utilization by cauliflower mitochondria in the presence of malate, trace *A*, and reduced diphosphopyridine nucleotide, trace *B*. Malate = 0·005 *M*, 2·5 mgm. reduced diphosphopyridine nucleotide added, conditions as in Fig. 1

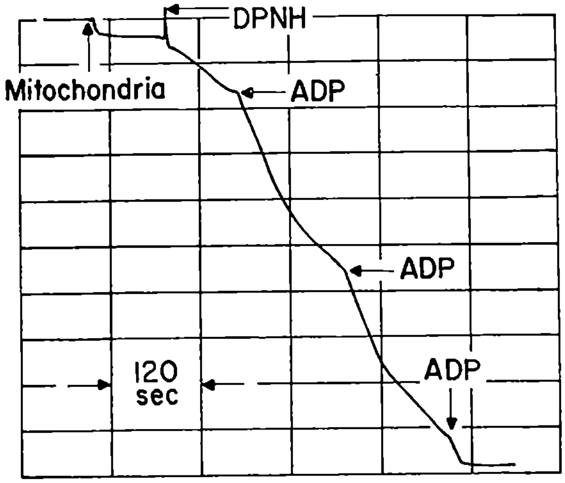

Fig. 3. Polarograph trace of the oxygen utilization by sweet potato mitochondria in the presence of reduced diphosphopyridine nucleotide and adenosine diphosphate. 2·5 mgm. reduced diphosphopyridine nucleotide added, conditions as in Fig. 1

by adenosine diphosphate depends on several factors, one of which is the careful separation of the mitochondria from the starch fraction.

Cauliflower (*Brassica oleracea*) and sweet potato (*Ipomea batatas*) have been shown to be excellent chlorophyll-free sources for mitochondrial investigations[1,2,4] and are easily obtained from local markets in some places.

Mitochondria were isolated in the following manner. 150 gm. of cold, diced tissue were ground in a Waring blendor for 5 sec. in 300 ml. of grinding medium. The grinding medium consisted of 0·6 *M* mannitol, 0·6 *M* sucrose (75 per cent mannitol, 25 per cent sucrose), 0·5 per cent cysteine (free base), and 10^{-3} *M* versene. The *p*H of the medium was 7·2. The partially disintegrated tissue resulting from the treatment in the Waring blendor was ground in small aliquots in an unglazed porcelain mortar, the grinding being continued until a smooth paste was obtained. The disintegrated tissue was squeezed through muslin and the resulting suspension was centrifuged at 1,000*g* for 5 min. The mitochondria were then sedimented by centrifuging 7 min. at 10,000*g*. The mitochondria were washed twice in the mannitol–sucrose mixture but without the addition of cysteine or versene. After each washing the sedimented mitochondria must be separated carefully from the starch fraction. The *p*H of all suspensions is one very critical factor in the preparation of mitochondria from cauliflower. With cauliflower, the *p*H must be kept between 7·2 and 7·5; with sweet potato, the *p*H is not such a critical factor.

Sweet potato and cauliflower mitochondria actively oxidize a few substrates. Fig. 2*A* shows the time-course of malate oxidation by cauliflower mitochondria, and it may be seen that the presence or absence of adenosine diphosphate considerably alters the rate of oxidation. In marked contrast to intact mitochondria from animal tissues, the plant mitochondria not only rapidly oxidize malate but also reduce diphosphopyridine nucleotide. The rate of oxidation of reduced diphosphopyridine nucleotide is also controlled by the presence or absence of adenosine diphosphate (Figs. 2*B* and 3). This control has been obtained in mitochondria derived from sweet

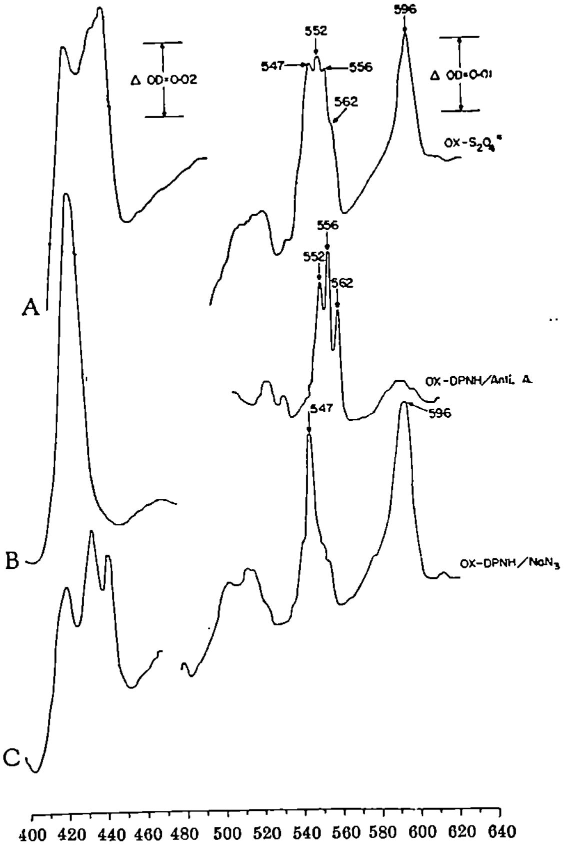

Fig. 4. Low-temperature (–190° C.) difference spectra of sweet potato mitochondria. Curve *A*, the difference in absorption between oxidized and hydrosulphite-reduced mitochrondria. Curve *B*, the difference in absorption between oxidized mitochondria and mitochondria reduced with reduced diphosphopyridine nucleotide in the presence of antimycin *A*. Curve *C*, the difference in absorption between oxidized mitochondria and mitochondria reduced with reduced diphosphopyridine nucleotide in the presence of azide

potato, potato (*Solanum tuberosum*), cauliflower, broccoli, beetroot and cucumber. It would seem that the oxidation of 'external' reduced diphosphopyridine nucleotide is a phenomenon common to plant tissues, and represents one of the marked differences between plant and animal mitochondria.

The cytochrome components of sweet potato mitochondria have been delineated through the use of a sensitive rapid scanning split-beam spectrophotometer[5] adapted for use at low temperature[6]. The spectra were obtained in the absence of glycerol as described by Bonner[7]. Low-temperature spectrophotometry allows increased absorption and increased delineation, afforded by the sharpening of absorption bands at such temperatures[8]. A low-temperature difference spectrum between aerobic and hydrosulphite-reduced sweet potato mitochondrial suspensions shows maxima at 596, 562, 556, 552 and 547 mμ (Fig. 4*A*). A similar spectrum of the difference in absorption between aerobic mitochondria and mitochondria reduced with reduced diphosphopyridine nucleotide in the presence of antimycin *A* shows maxima at 562, 556 and 552 mμ (Fig. 4*B*). Finally, a difference spectrum between aerobic mitochondria and mitochondria reduced with reduced diphosphopyridine nucleotide in the presence of azide shows two main peaks at 596 and 547 mμ (Fig. 4*C*). These difference spectra show maximum absorption at 596 and 547 mμ, corresponding to the maxima of cytochromes $a + a_3$ and c respectively. Since the maxima at 562, 556 and 552 appear in the spectrum obtained in the presence of antimycin *A*, they are interpreted to represent the absorption maxima of three different b cytochromes.

The cytochromes of sweet potato mitochondria appear to be identical to those which have been described in mitochondria derived from a variety of plant tissues[7]. The cytochromes present in higher plant mitochondria are remarkably similar among plant species, but show marked differences from animal mitochondria, especially in the nature of the b components. It is our hope that the preparation of reasonably intact mitochondria, as described here, will provide the much-needed material for the characterization of the respiratory chain in plants.

GIBBERELLIN-LIKE SUBSTANCES IN PLANTS

By MARGARET RADLEY

Imperial Chemical Industries, Ltd., Pharmaceuticals Division, Akers Research Laboratories, Welwyn, Herts

Leguminous Root Nodules

IT has been shown[1] that in clover excision of the first-formed nodules, and also of the root-tips, stimulates further nodulation. Plants grown in association[2] or in succession[3] on a limited volume of medium can inhibit nodulation of an inoculated leguminous plant. The donor of the inhibiting effect need not be a leguminous plant. When charcoal[4] is added to the rooting medium, nodulation-rate is stimulated. It has also been shown that root-nodule formation on leguminous plants is reduced in *Phaseolus*[5,6] and in some species of *Trifolium*[7] by treating the foliage with gibberellin.

The content of endogenous gibberellin-like substances in nodules and roots has now been examined by the bioassay of extracts of these tissues. The extractions were carried out with ethyl alcohol, and the solutions were purified as previously described[8]. The extracts were then applied in alcohol to the leaves of dwarf pea seedings (var. Meteor). The growth of these plants was compared with others treated with known amounts of gibberellic acid.

Table 1 gives the results of three experiments using French beans and garden peas. The first experiment was carried out with young bean seedlings, one month old. In the second experiment old plants, from which pods had been gathered, were used. In neither case was any gibberellin-like activity detected in the roots, whereas a high concentration was found in the nodules. Dwarf and tall varieties of pea were compared. In both cases a low concentration of active substances was detected in the roots and a high concentration in the nodules. The nodules of the dwarf variety appeared to be particularly rich in these substances.

In addition, two small-scale experiments were carried out with French bean plants grown in water culture with and without inoculation with *Rhizobium*. In one experiment the nodulated roots and the culture solution in which they were grown both contained material with gibberellin-like activity, whereas none was detected in the uninoculated sample. In the other experiment the same amount of activity was found in the shoots of both groups of plants and some activity in the nodules of the inoculated plants, but none was found in the roots or the culture solutions of either group.

No activity was detected in a 2-gm. sample of root tips from 3-week-old French beans grown in soil;

Table 1. GIBBERELLIN-LIKE ACTIVITY IN ROOTS AND NODULES

Species	Tissue extracted (gm.)	μgm. gibberellic acid equivalent per kgm. tissue
I. *Phaseolus vulgaris* var. Masterpiece	Nodules 8·2	9·8
	Roots 8·2	0
	,, 24·9	0
II. *Phaseolus vulgaris* var. Masterpiece	Nodules 8·2	17·1
	,, 16·8	26·2
	Roots 8·2	0
	,, 108·5	0
III. *Pisum sativum* var. Meteor	Nodules 0·3	240
	Roots 0·3	0
	,, 69·3	0·2
var. Improved Pilot	Nodules 0·26	35·4
	Roots 0·26	0
	,, 59·7	0·93

but French bean seedlings grown in water culture secreted material with gibberellin-like activity into the culture solution for at least two weeks after germination. At least 0·01 μgm. gibberellic acid equivalent per plant was detected. Runner beans, peas, wheat and radish secreted smaller quantities into the culture medium.

These results suggest that the nodule-inhibiting factor produced by nodules and root tips is probably a gibberellin, and this may diffuse out into the surrounding medium in some circumstances.

The plants inoculated with *Rhizobium* in water culture were provided by Mr. W. K. Smith.

Seaweed (*Fucus vesiculosus*)

ALTHOUGH gibberellin-like substances have been found in many species of flowering plants, none has yet been reported from lower plants, apart from the fungus *Gibberella fujikuroi* and the yeast *Candida pulcherrima*[1]. Nevertheless, there are reports of a response to applied gibberellin in ferns[2,3], a moss[4], a liverwort[5] and green algae[6,7], suggesting that gibberellins may play some part in regulation of growth. A substance with gibberellin-like activity has now been shown to occur in a seaweed.

4,000 gm. of *Fucus vesiculosus* was collected and stored at − 18° C. For the first experiment 500 gm. was extracted with ethyl alcohol for 18 hr. at room temperature. The alcohol was removed by filtration and pressing, and the tissues were re-extracted with fresh 70 per cent aqueous alcohol for 4 hr. The alcoholic solutions were combined and were then treated as previously described[8]. The purified extracts were applied in alcohol to the leaves of dwarf pea seedlings of the variety Meteor. Three doses of the extract were compared with known amounts of gibberellic acid. This test was carried out in duplicate, one batch of plants being grown in a greenhouse in the natural lighting conditions of July, and the other batch grown under continuous artificial light only at a temperature of 15° C. The results are given in Table 1.

Table 1. GIBBERELLIC ACID EQUIVALENT (μGM./KGM. FRESH WEIGHT)

Fresh weight equiv. of extract (gm.) per plant	Bioassay conditions Greenhouse	Artificial light
50	7·2	0·76
10	12·0	2·1
2·5	6·8	5·2

Thus all extracts promoted growth considerably; this is evidence for the presence of gibberellin-like substances. The relative decrease in activity in the higher doses tested, when the plants were receiving artificial illumination, suggested that inhibitors might be interfering with the response.

The remaining 3,500 gm. of material was then extracted twice with alcohol, filtering but not pressing the tissue each time, and the alcoholic solution was concentrated in a climbing film evaporator. The acidic fraction of this was adsorbed on to a column of charcoal/'Celite' (5 : 1), and was eluted with water containing increasing amounts of acetone. Six fractions were recovered from the aqueous acetone and were dissolved in ethyl alcohol.

In a preliminary series of bioassays aliquots of all eluates were concentrated and applied to dwarf pea plants. Gibberellin-like activity was found only in the 50 per cent acetone eluate. In a similar experiment carried out under artificial light in which 1·0 μgm. gibberellic acid was added to each eluate it was found that the 90 per cent acetone eluate (an aliquot equivalent to 100 gm. of tissue) reduced the response to gibberellic acid to about half that expected; there was no evidence for the presence of an inhibitor in the 50 per cent acetone eluate.

The 50 per cent acetone eluate was then bioassayed at three dosage-levels (Table 2). The lower level of activity found, compared with that recorded in Table 1, may have been due to loss in storage or to less-efficient extraction. Part of this eluate was chromatographed on paper in *n*-butanol/1·5 N ammonia (3 : 1). The paper was divided into 10 parts, eluted with alcohol and bioassayed on dwarf peas. All the activity was found between R_F 0·3 and 0·4. Under these conditions the R_F of gibberellic acid was 0·38 and that of gibberellin A_5 was 0·59. The other known gibberellins with a similar R_F to gibberellic acid are gibberellins A_1 and A_6 (ref. 9); thus the active material present in *Fucus vesiculosus* may be one of these.

Table 2. GIBBERELLIC ACID EQUIVALENT (μGM./KGM. FRESH WEIGHT)

Fresh weight equiv. of extract (gm.) per plant	Bioassay conditions Greenhouse	Artificial light
125	0·45	0·36
25	0·52	0·40
4	trace	trace

Chromatograms of the 90 per cent acetone eluate were run in the same solvent system. An inhibitory substance present at R_F 0·6–0·7 was demonstrated by a lettuce germination test and by the lettuce seedling assay[10] in which the response to gibberellic acid was reduced. On the other hand, there was no significant reduction of the response of dwarf peas to gibberellic acid, and it is not clear whether this is in fact the substance causing the reduction in gibberellin response in the earlier experiments. Inhibitor β, which is found in many higher-plant tissues, has a similar R_F in this solvent system[11,12]. An inhibitor of gibberellin-induced growth found in seed extracts has been described by Corcoran and Phinney[13]. Its mobility in this solvent system is not known.

AN ENDOGENOUS RHYTHM IN THE RATE OF DARK-FIXATION OF CARBON DIOXIDE IN LEAVES OF *BRYOPHYLLUM FEDTSCHENKOI*

By DIANA M. WARREN and MALCOLM B. WILKINS

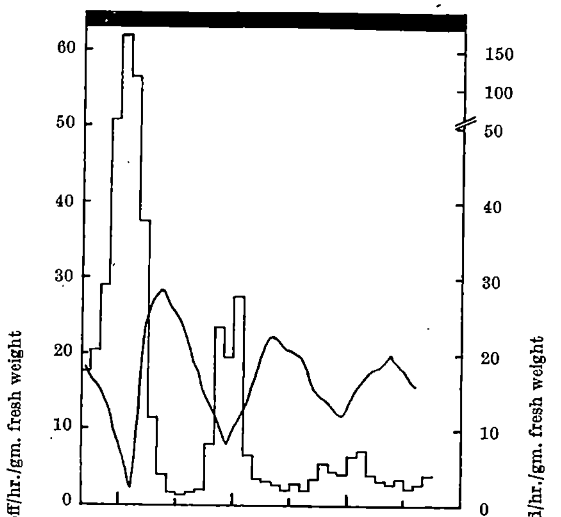
Department of Botany, University of London, King's College, 68 Half Moon Lane, London, S.E.24

LEAVES excised from the succulent plant *Bryophyllum fedtschenkoi* and maintained in darkness, at a constant temperature of 26° C., and in an air-stream initially free of carbon dioxide, exhibit an endogenous circadian rhythm in their rate of carbon dioxide emission[1,2]. The rhythm is inhibited by light but recommences when darkness is restored, the phase being determined by the time at which the light is extinguished. Furthermore, exposing leaves maintained in darkness to a light perturbation of 5 hr. duration at the crest of a peak has no effect on the phase, whereas a similar perturbation offered between the peaks induces a phase shift in which the first post-treatment peak occurs 18–19 hr. after the recommencement of darkness. The rhythm of emission of carbon dioxide is present in leaves excised from plants grown during long days and short days[1].

It has been suggested[1] that this rhythm may be due to the periodic activity of a dark, carbon dioxide fixation mechanism acting on an aperiodic rate of production of respiratory carbon dioxide by the tissue and the present work was designed to test this hypothesis.

The experimental plants were grown in cabinets in which illumination was provided by a Philips high-pressure mercury vapour lamp and four 150-W. tungsten lamps. Long-day illumination extended from 2400 hr. until 1600 hr. and short-day illumination from 0800 hr. until 1600 hr. The technique adopted in these experiments was as follows: three leaves were placed in each of a number of specially constructed glass tubes through which an air stream, initially free of carbon dioxide, passed at a rate of 1·5 l. per hr. The tubes were immersed in a water bath at 26° C. and illuminated at an intensity of 3,000 lux until darkness commenced. At 2-hr. intervals following the onset of continuous darkness, the flow of air free of carbon dioxide to one of the tubes was interrupted and $^{14}CO_2$ liberated in the closed tube. The concentration of carbon dioxide in the tube at the commencement of the 2-hr. feeding period was 0·66 per cent and the specific activity 88·4 µc./m.mole. At the end of the feeding period the tube was cleared of labelled carbon dioxide and the leaves were killed in boiling 80 per cent alcohol. They were then macerated and extracted successively with 80 per cent alcohol, 50 per cent alcohol and water, when no activity remained in the solid residue. The extract was reduced to a known small volume and the total carbon dioxide fixed by the leaves during the feeding period determined by estimating the radioactivity present in a sample of the extract. The uptake of carbon dioxide is expressed as µgm. carbon dioxide per hr. per gm. fresh weight of tissue. Simultaneous control experiments were conducted in which the rate of carbon dioxide output of two samples of leaves was monitored with an infra-red gas-analyser incorporated in an apparatus similar to that used in previous studies[1-3].

In the first two experiments leaves were excised from the plants between 1400 hr. and 1500 hr. and transferred to continuous darkness at 1600 hr., that



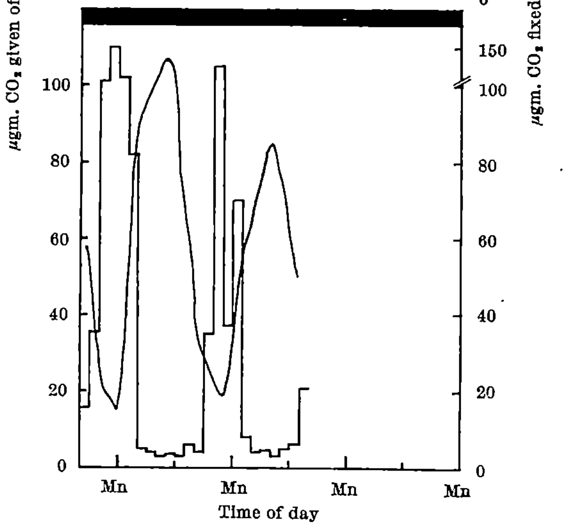


Fig. 1 (top). Rhythms in the rate of fixation (histogram) and output (continuous curve) of carbon dioxide in excised short-day leaves of *B. fedtschenkoi* maintained at 26° C. and in continuous darkness which commenced at 1600 hr. The black area of the bar above each figure indicates darkness. Ordinates, µgm. CO_2 fixed or given off/hr/gm. fresh weight of tissue; abscissa, time of day, Mn (midnight)

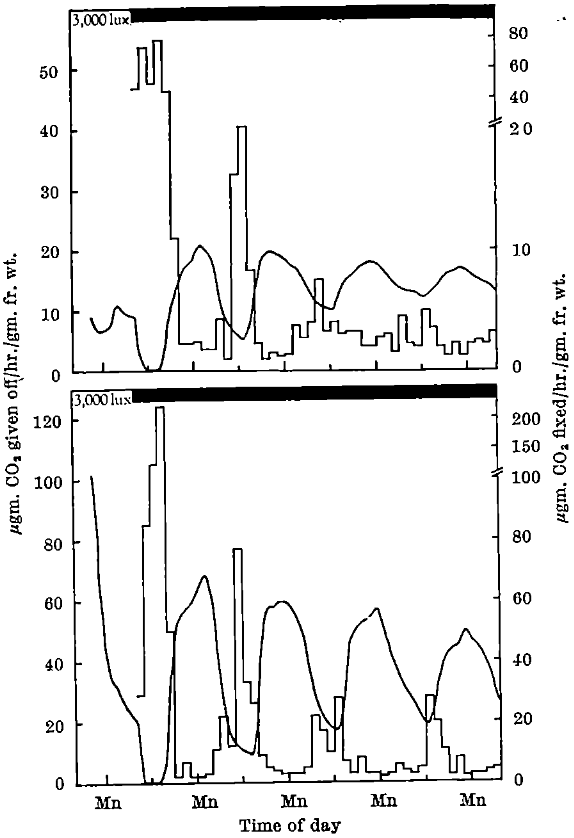
Fig. 2 (bottom). Rhythms of fixation (histogram) and output (continuous curve) of carbon dioxide in leaves taken from a plant grown in long days and transferred to darkness at 1600 hr.

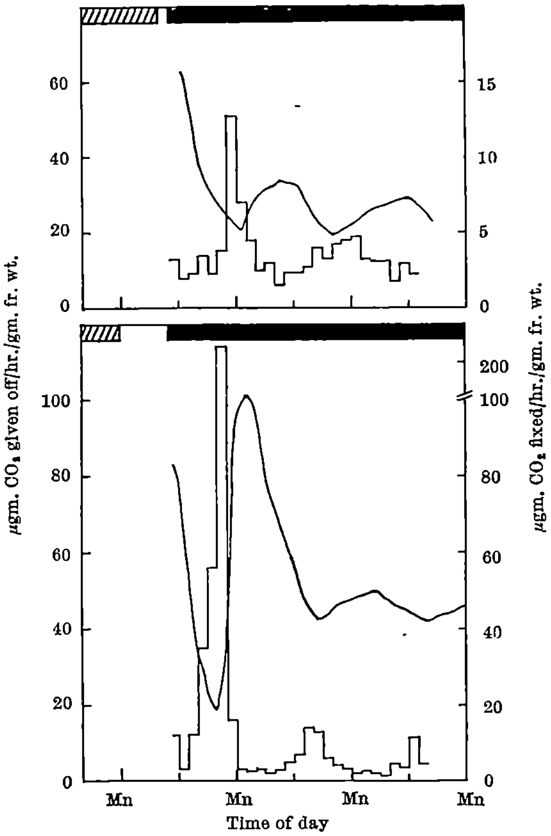


Figs. 3 and 4. Changes induced in the phase of the rhythms of fixation (histogram) and output (continuous curve) of carbon dioxide in short-day (Fig. 3, above) and long-day (Fig. 4, below) leaves by postponing the onset of continuous darkness from 1600 hr. to 0800 hr. the following morning

is, at the same time that darkness commences in the growth cabinets. The subsequent rate of dark fixation of carbon dioxide by short-day leaves showed a distinct rhythm in which the first peak occurred at 2400–0200 hr., 8–10 hr. after the onset of continuous darkness, and further peaks at intervals of approximately 23–24 hr. (Fig. 1). A similar result was obtained when this experiment was repeated with leaves taken from a plant grown in long days (Fig. 2). Continuous darkness again commenced at 1600 hr. and the first peak of the rhythm of fixation occurred approximately 8 hr. later at 2400 hr., with subsequent ones at about 23-hr. intervals. In each experiment the peaks of the rhythm of fixation occurred at times closely similar to the troughs in the rhythm of net output of carbon dioxide and vice versa. The slightly earlier occurrence of the first peak of the fixation rhythm in long-day leaves is consistent with a previous finding[1,4] that the transient in the output rhythm decreases as the duration of the previous light treatment is increased.

The phase of the rhythm of fixation of carbon dioxide can be changed if the onset of darkness, which normally occurs at 1600 hr., is postponed for several hours. Leaves were excised and placed in the tubes in the usual manner between 1400 hr. and 1500 hr. and then illuminated at an intensity of 3,000 lux until 0800 hr. the following morning. The rate of carbon dioxide fixation by both short-day (Fig. 3) and long-day (Fig. 4) leaves in the subsequent continuous darkness showed a distinct 23–24-hr. rhythm in which the first peak occurred at approximately 1400 hr., that is, about 6 hr. after the light was extinguished. Figs. 3 and 4 show that the rhythm of carbon dioxide fixation persists for at least 4 days in both short-day and long-day leaves held in darkness and at 26° C. In each figure the peaks of the fixation rhythm again occur at similar times to the troughs in the output rhythm.

In two further experiments the leaves were excised between 0800 hr. and 0900 hr. and transferred to darkness at 1000 hr.; both the short-day and the long-day leaves therefore experienced darkness 6 hr. earlier than if they had remained in the growth cabinets. It is clear from Fig. 5 that when short-day leaves are darkened at 1000 hr. the first peak of the rhythm of carbon dioxide fixation occurs at 2400–0100 hr. and the next peak 22–23 hr. later. The peaks occur, in fact, at the same times of day as those in the experiment shown in Fig. 1, where the leaves were darkened at 1600 hr. On the other hand, if long-day leaves are darkened at 1000 hr. the first peak of the fixation rhythm occurs at approximately 1900 hr., 9 hr. after the onset of darkness (Fig. 6), and subsequent ones at intervals of approximately 23 hr. It is clear, therefore, that while the early onset of darkness does not modify the phase of the rhythms of fixation or output of carbon dioxide in short-day leaves, in long-day leaves



Figs. 5 and 6. Rhythms of fixation (histogram) and output (continuous curve) of carbon dioxide in short-day (Fig. 5, above) and long-day (Fig. 6, below) leaves transferred to continuous darkness early in the day at 1000 hr. The hatched area of the illumination programme bar represents the darkness experienced by the leaves in the growth cabinets prior to the onset of the day (unshaded area) in which they were excised and darkened early. For explanation see text a phase shift is induced in which the first peaks of the fixation and output rhythms occur approximately 9 and 19 hr. respectively after the recommencement of darkness.

The invariable coincidence between the times of occurrence of the peaks of the fixation rhythm and the troughs of the output rhythm and vice versa in Figs. 1–6, irrespective of the time of day at which darkness commences, indicates that the rhythm of emission of carbon dioxide in the leaves is, in fact, a manifestation of the fixation rhythm re-fixing respiratory carbon dioxide at certain times in the cycle and not at others.

The induction of a phase-shift in the rhythms of both fixation and output of carbon dioxide by exposing long-day, but not short-day, leaves to darkness at 1000 hr. was to be expected on the basis of results already published[2,3]. If the onset of the dark period immediately prior to the day during which the leaves were transferred to darkness at 1000 hr. is considered as the time when continuous darkness commenced, then the curtailed day which the leaves received afterwards can be regarded as a light perturbation. In the case of long-day leaves this perturbation commenced at 2400 hr., that is, between the peaks of the rhythm of carbon dioxide output, and this would induce a phase-shift in which the first post-treatment peak would occur 18–20 hr. after the end of the treatment. In the short-day leaves the perturbation did not commence until 0800 hr., that is, until the crest of the peak of the output rhythm had been reached, and the phase of the rhythm is unaffected by a perturbation offered at this position in the cycle. Furthermore, the duration of the perturbation experienced by the long-day leaves was 10 hr., whereas that experienced by short-day leaves was only 2 hr.

Except when the leaves are, in effect, merely exposed to a light perturbation at the crest of a peak of the output rhythm, it is clear that the phase of the rhythms of output and fixation of carbon dioxide is determined by the time at which darkness commences and may be set accordingly at any desired time of day. Moreover, the results presented in Figs. 5 and 6, and those already published[2,3], show that the phase of the rhythms in leaves maintained in darkness is reset by a light perturbation only if it is administered in that part of the cycle where carbon dioxide fixation is occurring.

In attempting to locate the basic, oscillating chemical system in the leaf tissue it is important to determine whether the rhythm of carbon dioxide fixation is the only component of the output rhythm or whether there is also a rhythm in the rate of production of respiratory carbon dioxide. Preliminary experiments using the Warburg technique have not hitherto yielded evidence of a rhythm in the rate of respiration (oxygen uptake) of either whole or dissected leaves maintained in darkness and at 26° C. If the rate of production of respiratory carbon dioxide is aperiodic and corresponds to the rate of carbon dioxide emission of the leaves at the crests of the peaks of the output rhythm, then there should be a quantitative agreement between the maximum rates of fixation of carbon dioxide and the maximum decreases in the rates of carbon dioxide emission by the leaves in the corresponding troughs of the output rhythm. However, it is not possible to make a close quantitative comparison between the maximum rates of carbon dioxide fixation and the maximum decreases observed in the rate of carbon dioxide output of the leaves because, first, the rate of fixation of carbon dioxide by the leaves is a function of the ambient concentration of the gas, and secondly, the rates of fixation of carbon dioxide recorded in this work refer to the total fixation of the carbon dioxide liberated into the tubes and do not include the refixation of respiratory carbon dioxide which must occur during the 2-hr. feeding period when the leaves are incorporating the labelled gas.

The endogenous rhythm in the rate of dark fixation of carbon dioxide is undoubtedly the major component of the rhythm of carbon dioxide output in the leaves. Whether or not it is the only component is now the subject of a detailed investigation.

We thank Prof. T. A. Bennet-Clark for providing laboratory facilities for this work, and the Agricultural Research Council for financially supporting one of us (D. M. W.).

CALCULATION OF THE AREAS OF ISOLATED OR OVERLAPPING NORMAL PROBABILITY CURVES

By DR. D. MORISON SMITH and JOHN C. BARTLET
Food and Drug Directorate, Tunney's Pasture, Ottawa, Canada

A MATHEMATICAL method has been developed for the calculation of the areas of normal probability curves, even when they overlap one another[1]. The method was used in that paper for the analysis of gas chromatograms obtained with a differential detector system. It should be possible to apply this method to any display of overlapping curves which exhibit probability characteristics. There are many procedures in various fields which apparently give such displays besides gas chromatography; for example, there are the curves obtained on plotting a given chemical property versus emergence time or fraction number in column partition chromatography; the optical density curves obtained by photoelectric scanning either through an angle in X-ray spectrometry or over a wave-length in emission spectra or across the spots in the direction of their motion in paper chromatography or electrophoresis; the sedimentation diagrams obtained on the ultracentrifuge with materials of high molecular weight; and some mass spectrometry curves, particularly those obtained on machines using the time of flight principle. The optical density curves obtained from photographic plates of emission spectra or Debye–Scherrer X-ray diffractions may also be probabilistic in nature, but calculations for such curves will depend on variations in the photographic response with wave-length and intensity. There is also the possibility that this method might apply to some very simple, uncomplicated infra-red or ultra-violet spectra.

The first step in the application of this method is to determine whether isolated peaks fit the requirements for normal probability curves. From Sheppard's tables of the normal probability integral[2], it is found that the width of the normal probability curve equals one standard deviation, σ (sigma), at 0·882 of the peak height, h, equals 2σ at 0·607 h and 3σ at 0·324 h. If the curve conforms to a normal probability curve, the values of σ derived from measurements of peak-width will be constant. The area may then be calculated from the equation: area, $A = h\sigma\sqrt{(2\pi)}$.

For the determination of the areas of overlapping normal probability peaks, there must be some means of predicting the σ values these peaks would have if they were isolated. In the case of chromatographic processes, the distribution of a given compound is controlled by random mechanisms such as diffusion within a phase or transfer between phases. The repeated application of these random mechanisms leads to broadening the peaks (increased σ) as the process continues. In gas chromatography, when σ is plotted versus the retention times of the peaks, a straight line is obtained[1]. The work of Craig[3] indicates that the same increase in σ occurs in countercurrent distribution and in column chromatography. For other processes, σ may be constant, or depend on certain experimental variables, for example, width of slit in an optical system or angle from the incident beam, in a diffraction system. All the above variations of σ with time, fraction number, angle, slit width, etc., are experimental variables which can be correlated to values of σ in a calibration curve. Sigma can then be read from this curve and the σ values of overlapping peaks can be interpolated.

When two additive normal probability curves overlap, the contribution of one curve to the apparent height of the other can be calculated. The information necessary for this correction was obtained from Sheppard's tables[2]. For convenience, it is presented graphically on probability paper in Fig. 1 with the ordinate of the normal probability curve, converted to percentage of peak height, plotted against the distance between the peaks measured in units of σ.

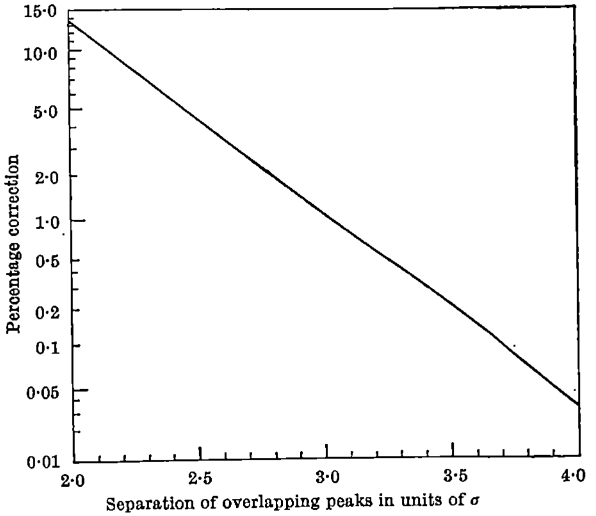

Fig. 1. Corrections of peak height for given separations of peaks measured in units of σ of the interfering peak

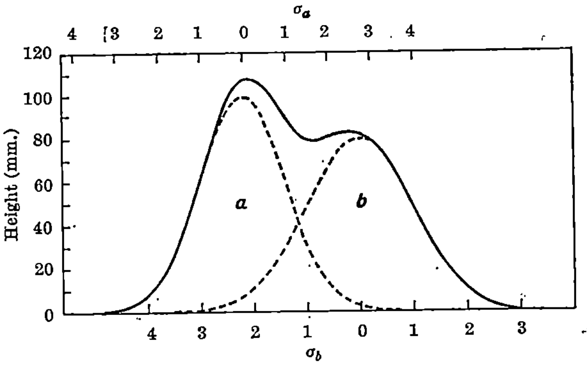

Fig. 2. Overlapping normal probability curves

A sample calculation of the mutual correction of two peaks is as follows. Consider the two peaks in the construction in Fig. 2. From previous experiments carried out under the same experimental conditions, either on the two isolated components for most accurate work, or on various mixtures, the values of σ and positions of the two peaks are interpolated. In the example under consideration, the values of σ obtained from a calibration graph are, for the first peak, (a) 20 mm. and for the second peak, (b) 25 mm.; the peaks are 55 mm. apart before photographic reduction for publication. The contribution of peak b to the height of peak a at the mean of peak a is dependent on the distance a is from b in terms of σ_b, which is 55/25 or 2·2 σ_b. This corresponds to a percentage contribution of 8·8 per cent of 82 mm., the observed height at b, that is, 7·2 mm. The observed height at a, 107 mm., is then corrected to 99·8 mm. by the deduction of the contribution of peak b. This figure is then used in the calculation of the true area of peak a. Similarly, the contribution of peak a to the height of peak b at its mean depends on the distance apart of a and b in terms of σ_a, which is 55/20 or 2·75 σ_a, corresponding to a contribution of 2·2 per cent of the 99·8 mm. of peak a or 2·2 mm. to be deducted from the height of peak b, giving 79·8 mm. for the true height of peak b. The construction actually used a height of 79·8 mm. for a and 99·7 mm. for b, giving an accuracy for the method within the limits of linear measurement on such a construction.

This accuracy was obtained with what is only the the first of a series of iterative corrections. It has also been observed that when the peaks are 4σ or more apart, no corrections need be made in the measured peak height.

It can be seen from Fig. 1 that there is a slight horizontal displacement of the observed peaks when they approach as closely as 2σ. The effect of this is insignificant; in fact, in many cases, if the peaks are separated enough to show as defined shoulders, direct measurement of height will give values by calculation for the areas which are within the inherent precision of the method itself.

This method may be extended to more than two peaks with the appropriate interrelated series of multiple corrections. Even with skewed probability curves, a similar treatment can be used to find the area of overlapping peaks[1].

Photography of Čerenkov Light from Extensive Air Showers in the Atmosphere

SEVERAL authors[1-4] have shown that Čerenkov light from extensive air showers in the atmosphere can be detected above the background light of the night sky, and that a single photomultiplier can be used for detecting showers of about 10^{15}-eV. primary energy at distances up to 600 m. from the shower axis.

We have used an image intensifier system, triggered by amplified pulses from a 5-in. photomultiplier, in an attempt to photograph the showers. The system consists of a Schmidt mirror 30 cm. in diameter, and nominal aperture of *f*0·5, but with usable area only 300 cm.². It has an acceptance cone of half-angle 17° about the zenith and is focused for infinity on the 5-in. diameter cathode of an image intensifier (Westinghouse *WX*4171). This is run continuously and integrates night-sky light over the decay time of the *P*15 phosphor, nominally 1 μsec. It is coupled optically to a three-stage cascaded intensifier (R.C.A. *C*73491) which is normally gated off, and which is followed by an intensifier orthicon, with kinescope display. The intensifier system has previously been used with a scintillation chamber and is described elsewhere[5]. Under present conditions we are limited by night-sky background, and operate the system well below full gain.

Light pulses are accepted by the photomultiplier over a cone of half-angle 50°, so that selection is isotropic over the field of view of the Schmidt system, but not all selected showers will be visible to it. Operation has been possible for 8 hr. under clear sky conditions and 32 shower pulses have been observed. A random pulse is applied a few seconds after each Čerenkov pulse, to obtain a comparison picture. Ten of the Čerenkov photographs have large spots, 3–5° in angular diameter. A typical event is shown in Fig. 1. No spots of comparable size or brightness have been observed in any of the 32 random pictures, though stars appear in both Čerenkov and random pictures. On covering the system, the field becomes dark. The evidence indicates that we are photographing the Čerenkov radiation from extensive air showers.

In the case illustrated, the first-magnitude star α Lyræ (Vega) also appears in both exposures, and this can be used to set a lower limit for the brightness of the shower pulse. It is known from previous work with the system that the effective integration time of the first phosphor is approximately 10 μsec., about ten times the nominal decay-time of the fast component. The total visible flux from the star during this time is roughly 10 photons/cm.². From the film density we estimate that the intensity of the shower pulse is of the order of 50 photons/cm.², consistent with a shower size of 10^5 particles. Accurate estimates are difficult because of non-linearities in the kinescope display and film response.

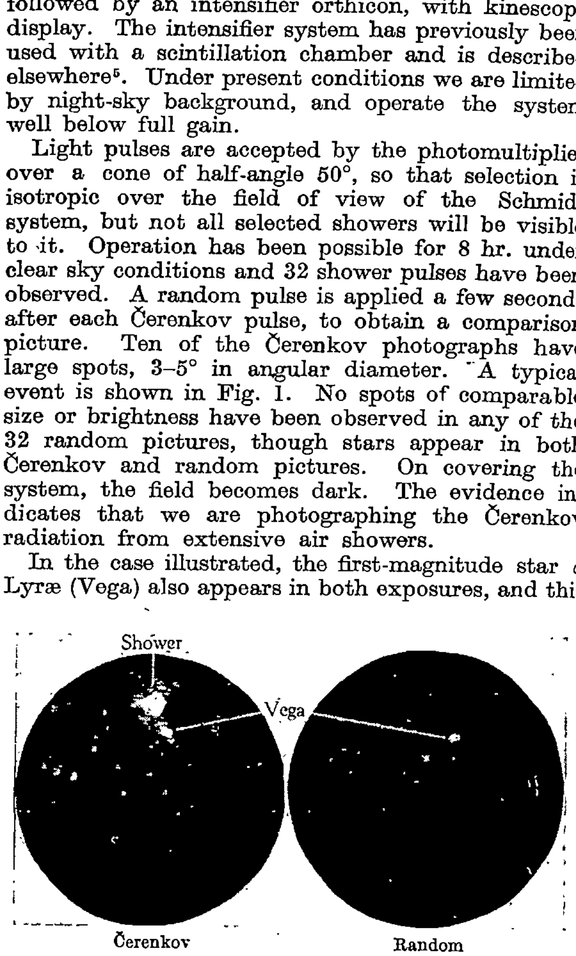

Fig. 1

The centres of the shower spots, which correspond presumably to the directions of the showers, can be determined with accuracy better than 0·5°. This combination of high directional precision with relatively high detection-rate suggests that the technique may be of value in the search for showers initiated by primary γ-rays.

The work was carried out at the Agassiz Observatory of Harvard University (100 m. above sea-level) and we would like to thank the Committee of the Observatory for allowing us the use of an astronomical building as well as Mr. K. Richards for his help in constructing and operating the system. One of us (N. A. P.) thanks the O.E.E.C. for the award of a senior visiting fellowship at the Massachusetts Institute of Technology. The experiment was supported in part through A.E.C. Contract *AT*(30-1)—2098, by funds provided by the U.S. Atomic Energy Commission, the Office of Naval Research, and the Air Force Office of Scientific Research.

An Autoradiographic Effect

WHILE using X-ray films in another investigation, autoradiographic effects were obtained from many ordinary substances or mixtures of them. Materials such as zinc metal powder alone or mixtures of metal powders in a medium such as dried 'Glyptal' varnish were used. Such mixtures were put in holes in wooden or plastic blocks and the films attached to the blocks with drawing-pins or tape. A cardboard separator was used around the edges of the blocks to keep the films out of contact with the materials, leaving an air-gap of about 1 mm. Exposures of 48 hr. were generally used.

The combination of materials used in most of these experiments was a mixture of aluminium filings in 'Glyptal' varnish with addition of small amounts of castor oil sometimes. The following experimental

Average temperature

Fig. 2

results are for such mixtures, but similar results were obtained from mixtures of other materials and also from metal filings or powders alone, notably zinc. Metal powders are not necessary for the effects, for they were also obtained from mixtures of organic materials.

The following series of experiments were performed to find out their effect on the autoradiations that were obtained:

Effect of ambient atmosphere on the radiation: Blocks were made up and exposures made in different atmospheres. The block, in each case with film attached, was put in a box impervious to light and placed in a bell jar in which the atmosphere was changed for each exposure. Results are shown in Fig. 1. All exposures were from the same block and were for 48 hr. The pressure in each case was a full atmosphere, except for vacuum, which was about 25μ or what is obtained from a rotary oil vacuum pump. There was no 'out-gassing' of the materials. Gases used such as argon, helium and krypton were taken from supplies used for lamp making and were dry. Hydrogen was dried with a small tube containing phosphorus pentoxide.

It may be noted that the kind of atmosphere affects greatly the kind of radiation results obtained from the same materials. The intensity is changed, and in some cases the wood of the block is made to radiate as shown in the case for vacuum. The highest intensity was obtained for hydrogen. The effect of additions is shown here, because the lower spot was from the mixture with a few per cent castor oil, while the upper one had no castor oil.

Effect of ambient temperature: The effect of ambient temperature is shown in Fig. 2. The same block was used for all cases. It may be noted that ambient temperature changes the results as to intensity of radiation and also the areas of the block which produce the radiation. At the first two temperatures the spot radiates as a whole, but at the third the radiation comes mostly from the edges of the spot.

Transfer of radiation: This is an effect which was found to occur if exposed, but not developed, films were stored next to each other for as much as 24 hr. This effect was studied by itself, and the results are shown in Fig. 3. On the left side are original radiations from the blocks, but on the right side are results from films which were not exposed to blocks, but were left in contact with the films on the left before they were developed. The time of such contact was 24 hr. or more. As shown, definite transfers were made and it should be noted that the transfers are not in proportion to the intensity of the original films. This would indicate that the agency causing the transfer is not the same as that which affects the X-ray film. Such transfers were obtained from materials other than films exposed to the radiating blocks, such as sheets of gelatine and metal foil.

Attempts were made to produce such transfers from films exposed to known radiations such as ordinary light, X-rays (about 1·5 Å.), β-rays from tungsten-185, γ- and β-rays from iron-59 and infra-red light. In all cases the original films (except the infra-red) had images comparable with those obtained from the blocks, but no transfers were obtained. The film is not sensitive to infra-red.

Experiments were performed to find out how long the originally exposed film would produce such transfers. A film was exposed to a radiating block for 48 hr. It was then left in contact with various other films which were changed at 24-hr. intervals. The results are shown in Fig. 4. The original film is on the left and the others are the films that were in contact with the original for the first 24 hr., second 24 hr., third 24 hr. respectively. The third film did not reproduce, but the images were discernible in the negative. Thus the activity of the original film persisted for 72 hr. or more.

It should also be stated that, for the transfer, the two films have to be as close as 1 or 2 mm. between them.

Fig. 1. Film exposed to hydrogen peroxide vapour for 1 hr.
Fig. 2*a*. As in Fig. 1
Fig. 2*b*. 'Transfer' from 2*a*. Time of transfer, 22 hr.

Range of radiation: This, of course, depends on the materials involved. Exposures at a distance of 3 in. produced the effect on the X-ray film. Using the usual extrapolation techniques, the indication is that the radiation may extend to as much as 6 in. Also at 3 in., the same results were obtained with the radiating materials above, below or to one side of the films. It is considered that this would not occur if the effect were due to a gas or vapour.

Also, the effect on the X-ray film has been obtained through thin sheets of aluminium foil, mica and up to 0·5 mil. 'Mylar' sheet. Whether the actual original radiation goes through these materials is open to question, for it may be another case of transfer as described here, the intervening materials re-radiating to the film on the other side.

Life of the radiating bodies: Experimental results indicate that, so long as the materials remain in the same condition, they will continue to radiate in the same way. Since, however, some oxidize, others such as plastic materials polymerize and set, etc., their radiating characteristics change.

All films referred to as X-ray films were Eastman 'No screen' X-ray films. A few attempts were made to use other films such as 'Tri*X*' and 'Panatomic', but without success.

The literature as listed here[1-3] mentions the 'Russell effect', which ascribes the effect of various materials on photographic films to the production of hydrogen peroxide, which reacts chemically with the films to produce the effect. In those cases ordinary films were used, and there is no doubt that hydrogen peroxide affects the films. In the above work, the effects were obtained only on X-ray film and were obtained under conditions such as vacuum, inert atmosphere and time where no such peroxide would be formed. This would indicate the presence of a radiation of a type for which these X-ray films are designed. It is therefore suggested that these radiations are a soft electron or β-type radiation with a range of as much as 6 in. from the source. The agency producing such radiations is somewhat obscure. It would have to be something which depends on the kinetic condition of the source, since production of the radiations is varied by conditions such as atmospheric content and pressure, vacuum, temperature, etc. More experimental work is needed to determine the exact nature of the agency causing these radiations.

Stuart McLean

Lamp Research and Development
Operation,

[2] Grunberg, L., and Wright, K. H. R., *Nature*, **170**, 456 (1952).
[3] Meleka, A. H., and Barr, W., *Nature*, **187**, 232 (1960).

We wish to report the following experiments which were designed as a consequence of McLean's observations reported here.

In our experiments we also used X-ray film, Kodak 'Crystallex', which is a standard material for X-ray diffraction work. Two series of experiments were carried out. In the first, the film was exposed for various times to hydrogen peroxide vapour by placing it above a dish containing the liquid. The film was then processed in the normal way. An example is shown in Fig. 1. (Compare with Fig. 1 of McLean.) In the second series of experiments a film which was exposed to hydrogen peroxide vapour, but not developed, was placed in contact with a fresh film. The two films were then developed and a transfer effect was observed as can be seen in Fig. 2*a* and 2*b*. (Compare with Fig. 3 of McLean.) We believe that the vapour particles attached to the original film were transferred to the second, resulting in the same effect as in the first series of experiments.

We made no attempt to reproduce McLean's 'transmission' effect using hydrogen peroxide; little information is given in the original work. It would be interesting, for example, to have such data as the porosity of the aluminium foil used, also the relative intensities obtained.

Initial Vibrations of a Supported Beam

The theory of steady flexural vibrations of a supported beam is well known, but that concerning the initial vibrations produced by impact seems to have received little attention. We have therefore carried out experiments on the subject.

Flexural vibrations of metal strips were initiated by striking the strips normally to the greatest area with pendulum-type hammers. The vibrations were examined by using a variable-reluctance transducer coupled through an amplifier to an oscilloscope. The movable component of the transducer was fixed to the beam or was formed by the beam itself when steel ones were used. The conversion characteristics of the transducer were found to be nearly constant with frequency for the small amplitudes of vibrations obtained in the experiments. The metal beams were all 2·54 cm. × 0·318 cm. × 40 cm., and were supported on knife-edges placed as closely as possible to their ends. Hammers made of various materials were used and were shaped to give approximately point contacts on the beams. Soft hammers, such as those made from cork or rubber, were found to result in a single impact, as shown by George[1] and Cliffe[2] for soft hammers striking pianoforte strings.

Figs. 1 and 2 show the oscilloscope trace obtained when a mild-steel beam was struck by a soft hammer at its centre, where the transducer was also located on the reverse side of the beam. In Fig. 1 the small timing pulses are spaced at intervals of 20 msec.

while in Fig. 2 the pulse spacing is 2 msec. In these figures the first apparent half-cycle of the fundamental mode of vibration is clearly seen to be of smaller amplitude and of shorter duration than the subsequent half-cycles. The same features were found in many of the photographs obtained by altering the positions of the transducer and the impact and by using beams of different metals.

The impulsive force acting at the hammer is not known, and attempts will be made to elucidate the force–time relationship which exists during impact, but the anomalous first half-cycle can be explained by assuming a form for the impulsive force and then following the method of Carslaw and Jaeger[3]. The force P_t acting at the centre of the beam due to the hammer is assumed to be given by $P_t = P_0(\exp(-at) - \exp(-bt))$, where P_0, a and b are all large positive constants and P_t is the force at time t. Fig. 3 shows graphs of $\exp(-at)$ and $\exp(-bt)$ from which a graph giving $(\exp(-at) - \exp(-bt))$, and hence the form of the impulsive force, can be constructed. Such a form agrees with that suggested by Goland *et al.*[4], although the ways in which impacts were obtained in this earlier work are different from those in the present experiments.

The displacement y_t of the centre of the beam at time t is then given by:

$$y_t = A_1\cos(kt) + B_1\sin(kt) + A_3\cos(9kt) + B_3\sin(9kt) + A_5\cos(25kt) + B_5\sin(25kt) + \ldots + A_n\cos(n^2kt) + B_n\sin(n^2kt) + \ldots - C\exp(-at) + D\exp(-bt) \quad (n \text{ odd})$$

where k, A_n, B_n, C and D are positive constants. k depends on the elasticity and dimensions of the beam. If $y_t = 0$ at $t = 0$, A_n, C and D are related by:

$$A_1 + A_3 + \ldots + A_n + \ldots - C + D = 0$$

Other considerations suggest that the amplitudes A_n and B_n are inversely proportional to the square of n. Thus, a simplified synthesis of y_t using only the terms having coefficients A_1, B_1, C and D may be expected to yield a fair representation of the actual y_t.

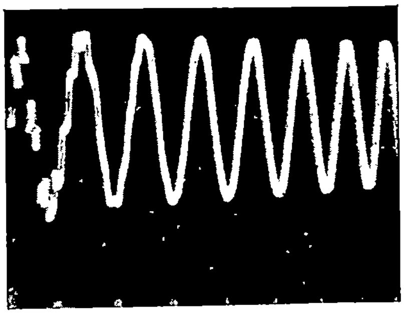

Fig. 1. Oscilloscope trace, timing pulse spacing 20 msec.

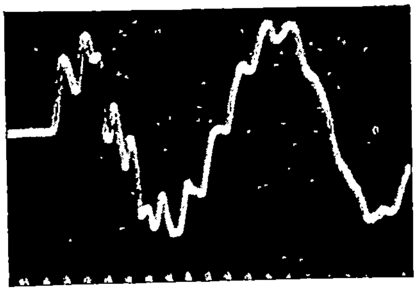

Fig. 2. Oscilloscope trace, timing pulse spacing 2 msec.

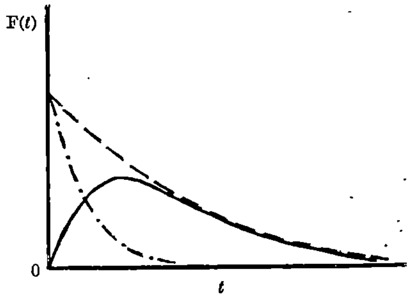

Fig. 3. Graphs of exp(−*at*), exp(−*bt*) and exp(−*at*) − exp(−*bt*). — —, exp(−*at*); —·—, exp(−*bt*); ——, exp(−*at*) − exp(−*bt*)

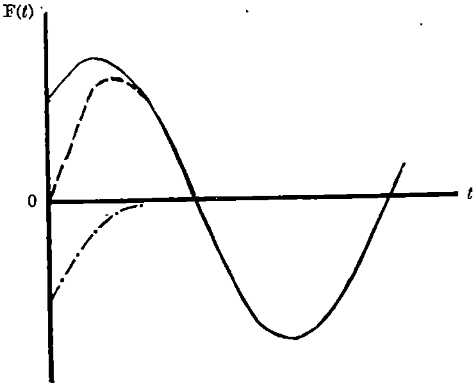

Fig. 4. Graphs of $A_1\cos(kt) + B_1\sin(kt)$, $D\exp(-bt) - C\exp(-at)$, and $A_1\cos(kt) + B_1\sin(kt) + D\exp(-bt) - C\exp(-at)$. ——, $A_1\cos kt + B_1\sin kt$; —·—$D\exp(-bt) - C\exp(-at)$; - - -, $A_1\cos kt + B_1\sin kt + D\exp(-bt) - C\exp(-at)$

Such a synthesis is given in Fig. 4 in which the sine and cosine terms have been combined. This figure shows a marked similarity to Figs. 1 and 2 so that the assumption of the form of P_t is further justified. Additional justification could perhaps be obtained by analysing wave-forms such as those shown in Figs. 1 and 2, but the analysis is made difficult by the presence of the anomalous first half-cycle.

Ultrasonic Absorption of Polymer Solutions

It is well known that the presence of a small amount of low-absorption solute in a highly absorbing solvent will reduce the absorption of the solution by much more than would be expected from simple proportionality. This is the case for mixtures of benzene (high absorption) with methyl methacrylate (low absorption). Wada and Shimbo[1] have shown that if polymethylmethacrylate is added to a benzene–methylmethacrylate mixture the resultant absorption is higher than in the absence of the polymer, although

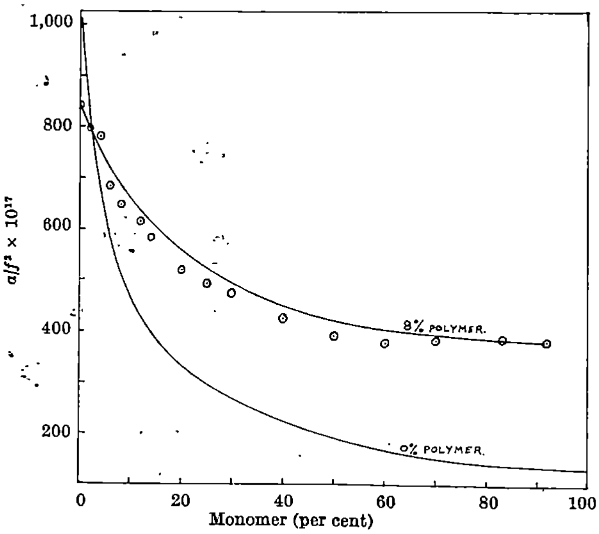

Fig. 1. α/f^2 as a function of monomer concentration. Full line, labelled 8 per cent polymer, predicted curve; dotted circles, experimental points

remaining less than that for the pure benzene. They suggested that this rise in absorption is caused by some of the monomer becoming 'enclosed' within the polymer chains so that it is no longer effective in reducing the solution's absorption. It is possible, however, to account for this rise in absorption without assuming 'enclosure'.

It is assumed that the absorption of a polymer – monomer – benzene mixture is made up of: (a) the absorption of a monomer – benzene mixture in which the polymer behaves in a similar manner to monomer in reducing the absorption; (b) an absorption due to the viscous motion of the solvent relative to the polymer chains[2,3]. This viscous absorption is assumed to be directly proportional to the mass of polymer present and the viscosity of the solvent. It is further assumed that these absorptions are additive. On these assumptions it is possible to account for the effects of the polymer found by Wada and Shimbo.

The ultrasonic absorptions of the mixtures have been measured at 26° C. and 5·19 mc./s. by a standard pulse technique. The measured absorption of 'Analar' benzene (expressed as α/f^2) is 1,010 × 10^{-17}, which is higher than the generally accepted value of 900 × 10^{-17}. However, for the present purposes, this discrepancy is unimportant since all the absorptions were measured under identical conditions with the same equipment.

The absorption due to the viscous motion of the solvent relative to the polymer chains was measured by comparing the absorption of a solution of polymethylmethacrylate in methylmethacrylate monomer with that of the pure monomer. Using monomer as solvent should probably eliminate any impurity effect which the polymer might have on the absorption. Expressed in terms of α/f^2 the viscous absorption of the polymer in monomer is 31 × 10^{-17} per gm. of polymer in 100-ml. solution. Thus, allowing for the higher viscosity of benzene compared with monomer, the expected value of α/f^2 for an 8 per cent (w/v) solution of polymer in benzene, in the absence of an impurity effect lowering the absorption, should be 1,310 × 10^{-17} while the measured value is 850 × 10^{-17}. The difference of 460 × 10^{-17} is that which would be produced by 6 gm. of monomer in 100 ml. of benzene solution. For 6 per cent and 4 per cent polymer solutions the corresponding equivalent monomer concentrations are found to be 3·8 gm. and 2·6 gm. of monomer in 100 ml. of solution. It appears, therefore, that the efficiency of the polymer, in so far as reducing the absorption is concerned, is about two-thirds that of the monomer (the actual values are 0·75, 0·63 and 0·65 respectively). This seems to be reasonable since the reduction in absorption by an impurity is due to collisions between it and the benzene molecules. If the monomer molecule is regarded as a cube there are six faces available for a collision with a benzene molecule, but when the monomer is connected into a polymer chain the number of faces available for collision drops to four for each monomer unit.

From a knowledge of the variation in α/f^2 and viscosity with monomer concentration in benzene – monomer mixtures and the amount of monomer equivalent to the polymer so far as reduction of absorption is concerned, it is possible to predict the variation in α/f^2 with monomer concentration for polymer – monomer – benzene mixtures. The results of one such calculation for an 8 per cent (w/v) solution of polymer are given in Fig. 1. The predicted curve lies consistently above the experimental points, showing that although the theory gives moderately good results it still requires improvement.

Molar Sound Velocity in Molten Hydrated Salts

FROM a systematic study of the temperature-variation of ultrasonic velocity and density in organic liquids, Rao[1] has found that the ratio of the temperature coefficients of the ultrasonic velocity and density is nearly equal to 3 for most organic liquids. From this result he has deduced the relation:

$$R = \frac{M}{\rho} (V)^{1/3}$$

where M is the molecular weight, ρ is the density, V is the ultrasonic velocity and R, known as molar sound velocity, is characteristic of the liquid and is independent of temperature. Although Rao established this relation in the case of organic liquids, later workers[2] have extended it to several inorganic liquids and have shown that R is independent of temperature. In the present communication, results are given of the variation with temperature of ultrasonic velocity in five molten hydrated salts.

The substances studied were lead acetate, sodium acetate, sodium–potassium tartrate, aluminium nitrate and calcium nitrate. For these substances the ultrasonic velocities in the molten state have been measured at various temperatures by using the fixed path interferometer method[3]. The variation of ultrasonic velocity with temperature for all salts is shown in Fig. 1. It will be seen that the variation of ultrasonic velocity with temperature is non-linear in all the salts except sodium acetate, which shows a linear decrease with increase of temperature. While investigating the variation of ultrasonic velocity with temperature in aqueous solutions of certain inorganic sulphates, Marks[4] found that the velocity–temperature curves are similar to those of water but displaced towards lower temperatures with increase in concentration. In the light of this earlier observation, the curves for the melts of sodium and lead acetates and calcium nitrate appear to be similar to the latter half of velocity-temperature curves of highly concentrated aqueous solutions, the maxima of which have been displaced considerably towards lower temperatures. It is interesting to note that the velocities in molten lead acetate are less than that of water. This behaviour is similar to that of other aqueous solutions of lead salts, as reported by Bärthel[5] and Krishnamurty[6]. The most unusual variation of ultrasonic velocity with temperature is observed in the case of double salt sodium–potassium tartrate, which shows a maximum at 75° C. which is very near the temperature of maximum velocity of water. A similar maximum is observed less prominently in the case of melt of aluminium nitrate. The behaviour of both these salts is unusual and needs further investigation in detail.

The values of molar sound velocity *R* are calculated at different temperatures, and it is found that for each salt *R* is independent of temperature. The maximum change, which is about 2 per cent, is observed only in the case of sodium–potassium tartrate. It may be noted that this temperature-independence of molar sound velocity has not been reported previously. Considering the molten hydrated salt as a highly concentrated aqueous solution of the salt in its own water of hydration and assuming linear variation of *R* with concentration at least in the higher concentration-range, the values of *R* for each salt are obtained by extrapolating to 100 per cent concentration and these values are given in Table 1. Computed values of *R* for the first three salts using previously estimated[7] values of *R* for the individual elements showed good agreement with the experimental values, thus justifying the procedure adopted here for calculating *R* for the pure salts from those of molten hydrated salts. The values of *R* for the last three salts in Table 1 are utilized for calculating *R* values for the metals aluminium, calcium and lead and have been given in the last column. It may be noted that the values of *R* for these three metals are obtained for the first time.

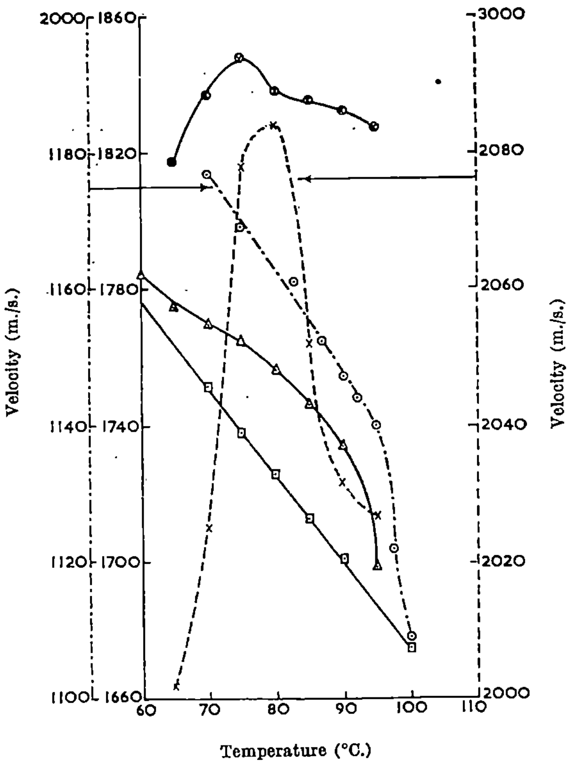

Fig. 1. Variation of ultrasonic velocity with temperature in molten hydrated salts. ⊗, Aluminium nitrate; ×, sodium potassium tartrate; △, calcium nitrate; ⊙, lead acetate; ⊡, sodium acetate

Table 1

Salt	Cm. (per cent)	*R* for hydrated salt	*R* for dehydrated salt	Computed value for salt	Computed value of *R* for new element
Sodium acetate	25	315	634	680	—
Sodium–potassium tartrate	20	438	1,350	1,329	—
Aluminium nitrate	10	295	1,060	—	Al = 319
Calcium nitrate	25	391	934	—	Ca = 436
Lead acetate	25	412	1,018	—	Pb = 127

Neutron 'Flux'

Mr. Stretch[1] objects to the use of the term 'neutron flux' because the entity specified is a scalar, the movement of neutrons involved being random instead of a directed flow; he contrasts this with the usage of the word 'flux' for a vector quantity. This usage, as in 'heat flux', is, however, already a degenerate form. Though now often used with a vectorial meaning, 'flux' was originally a scalar, albeit derived from a vector. The original meaning, which is still the customary one in electrical theory, is 'the surface integral of the normal component of a vector', and this is a scalar. It is this mathematical concept, surely, that should be the standard of orthodoxy.

The suggestion of replacing 'neutron flux' by 'neutron potential' is open to the objection that it already has a different meaning when considering the interaction of a neutron with another particle.

MINERALOGY

Basic Dyestuffs in Clay Mineralogy

BASIC dyestuffs are adsorbed on clay minerals by cation-exchange reaction. The amount of dye adsorbed[1] and the resulting colour transformations[2] provide a possible basis for identifying clay minerals, but they are not very reliable. We have found that clay mineral – dye complexes exhibit characteristic thermograms and this method may possibly be applicable to the identification of clay mineral. Certain clay minerals which exhibit similar thermograms can be differentiated by the thermograms of their dye complexes.

Four types of clay minerals, namely, kaolinite, illite, nontronite and montmorillonite, were each treated with excess of aqueous solution of malachite green, methylene blue, methyl violet or piperidine. The unadsorbed organic material was removed by filtration and thorough washing. Thermograms were obtained by carrying out the differential thermal analysis of the complexes semi-automatically, using a Leeds and Northrup programme controller. The rate of heating was maintained at 10 deg. C./min.

Thermograms of kaolinite, illite, nontronite and montmorillonite with three basic dyestuffs, namely, malachite green, methylene blue and methyl violet, have been investigated. Differential thermal analyses of piperidine complexes of clay minerals have also been carried out for comparison. All the complexes exhibit low-temperature exothermic peaks at about 100° C. smaller than those of the untreated samples. The organic matter probably occupies the spaces normally held by the water molecules.

Kaolinite–dye complexes exhibit a small unmistakable exothermal dent between 350° and 435° C. due to the oxidation of a small amount of dye adsorbed by base-exchange reaction. The exothermic peak of kaolinite–malachite green complex is much more intense than the other kaolinite complexes, because malachite green is adsorbed to a greater extent than other dyestuffs.

Illite – dye complexes (Fig. 1*a*) show two intense exothermic peaks between 200° and 500° C. Nontronite and montmorillonite – dye complexes (Fig. 1*b*) show three exothermic peaks, two of pronounced intensities.

The second exothermic peak in illite-complexes at 460°–470° C. is less intense than that of nontronite-complexes occurring at about 600° C. Illites can be differentiated readily from nontronites by the second exothermic peak.

In montmorillonite – dye complexes, the higher-temperature exothermic peak at 650°–670° C. serves to differentiate montmorillonites from nontronites and illites, in which it occurs at about 600° C. and 460°–470° C. respectively.

From differential thermal analysis and thermogravimetric analysis it is concluded that low-temperature exothermic peaks are caused by oxidation of the dye molecules adsorbed on the edges of the clay minerals, while the high-temperature exothermic peaks are due to oxidation of dye molecules adsorbed in the interlayer.

Thus differential thermal analysis of clay mineral – dye complexes provides a more efficient method of identifying clay minerals than that of the clay mineral – piperidine complexes suggested by Allaway[3], Byrne[4] and Carthew[5]. Such complexes exhibit pronounced exothermal inflexions. In addition, the kaolinite – dye complex also shows a distinctive exothermal dent.

GEOCHEMISTRY

Hot Spring Areas with Acid–Sulphate–Chloride Waters

WHITE[1], in a review of the thermal waters of volcanic origin, pointed out the problem of springs with a large flow of acid–sulphate–chloride water, such as Frying Pan Lake (or more correctly, Echo Crater) in the Waimangu area of the Rotorua-Taupo graben. This has a daily discharge of 800 kgm. of sulphuric acid. White remarked that the surface oxidation of hydrogen sulphide to sulphuric acid in the type of porous ground favourable to this process could account for only an insignificant part of the total production of sulphuric acid. Typical hot underground chloride water, as at Wairakei, is nearly neutral in reaction, and it seems unlikely that water appreciably acid could be stored underground without attack on the country rock. This communication suggests an explanation for the high-output acid–sulphate–chloride type of spring.

The second dissociation constant of sulphuric acid falls rapidly with rise of temperature. From data given by Noyes[2] from conductance determinations on 0·01 molar sulphuric acid up to 218° C., it appears that the second dissociation constant for 0·01 molar acid rises from approximately 5×10^{-6} at 250° C. to 0·019 at 20° C. If the water is neutral at 250° C., it will become acid at ordinary temperatures owing to increased dissociation of bisulphate by the reaction $HSO_4^- = H^+ + SO_4^{2-}$. The fall in *p*H due to this will outweigh the effect of the loss of carbon dioxide in the steam escaping from water reaching the surface. This means that sulphate waters which are neutral in *p*H underground at elevated temperatures can become waters of low *p*H at the surface.

Recently, chemical data have become available for the Rotokawa thermal area, about five miles east of Wairakei. This is an area with waters of acid character (*p*H about 2·5) containing both chloride and sulphate. Analyses of a number of hot-spring waters from Rotokawa indicate that there are two water types having chloride contents of 1,600 and 750 p.p.m. and sulphate contents of 400 and 1,000 p.p.m., respectively. The ionic ratios, chloride/sulphate, are about 10 and about 2 respectively. If the sulphate were of surface origin a random distribution of ratios would be expected. It is thought that both waters are supplied from deep underground sources.

It can be calculated for the Rotokawa examples that the *p*H of deep neutral waters (*p*H 5·65) at 250° C., containing 270 p.p.m. and 700 p.p.m. of total sulphate, would, after losing 30 per cent of steam at the surface, and cooling to 20° C., change in *p*H to 2·95 and 2·6 respectively. This is on the assumption that the content of bicarbonate in the underground water can be neglected. These *p*H values can be compared with those for a number of Rotokawa spring waters of low ammonia content. Three of the low-sulphate type had an average *p*H of 2·9 ± 0·4, and seven of the high-sulphate type had an average *p*H of 2·3 ± 0·15.

It seems, therefore, that some areas of acid springs of mixed chloride–sulphate water do not differ essentially in their origin from areas with springs of so-called 'alkaline' water (better termed chloride water). As there has not been any drilling at Rotokawa, it is not possible to obtain the ratio of chloride to total sulphur (that is, to sulphur both as hydrogen sulphide and as the sulphate) in the underground water but from the sulphate content alone it is at most 10. At Wairakei the ratio is 60. From other areas it is known that there are large differences in the ratios of chloride to boric acid, carbon dioxide, etc.

Hence the occurrence of waters of high sulphate content and low *p*H involves two problems: first that of the presence of a large amount of sulphur as sulphate (though not necessarily a larger proportion of the total sulphur), and secondly that of the low ratio of chloride to total sulphur.

Two possible mechanisms for producing chloride water high in sulphate can be suggested. First, the waters could result from the reaction of hydrothermal solutions with old sulphur deposits formed by oxidation of hydrogen sulphide near the surface, and buried by later volcanic activity. Disproportionation of sulphur in neutral solutions to sulphate and sulphide is predicted by thermodynamic information[3] and occurs readily in the laboratory.

The second mechanism is that hydrogen sulphide is oxidized to sulphate by ferric iron in the rocks. If the partial pressure of hydrogen in water in contact with iron-containing rocks is defined by the co-existence of hæmatite and magnetite, for equilibrium at temperatures over 250° C. in waters of neutral *p*H the sulphate/sulphide ratio is high[3]. This assumes that conditions prevailing correspond to a point on the phase diagram[4] where iron oxides rather than sulphides are the stable phases. For this to be the case at the likely hydrogen sulphide pressures of around 10^{-2} atmosphere, high temperatures probably more than 300° C. are necessary. Although iron sulphides become stable at lower temperatures as the water approaches the surface and loses steam, reversion of sulphate to sulphide is a slow process, and will not cause the loss of much sulphur from solution.

The first process would explain the low ratio chloride/total sulphur but is a less-likely occurrence. The second explanation makes the problem, apart from the possible requirement of high temperature, part of the general problem of the occurrence of deep chloride waters with great differences in the ratios of chloride to total sulphur, to carbon dioxide, to boric acid and to fluoride.

The analyses of the waters were made by Mr. W. A. J. Mahon, of the Dominion Laboratory.

BIOPHYSICS

An Invariant Casein Substrate for Rennet Standardization, derivable from Diverse Sources of Cows' Milk

When rennin or commercial rennets (impure rennins) cause milk to coagulate, it is well known that the primary enzyme action consists in decomposing a part only of the casein, known as κ-casein[1]. Later, either through the activity of the products of decomposition or through loss of protective action, the casein aggregates and finally a gel (curd) is formed.

We have recently shown[2] that the initial decomposition as indicated by the fall in viscosity (Ostwald viscometer) follows a first-order equation under normal conditions. (At the concentrations used, all solutions are Newtonian.) The logarithmic reaction constant (k) is proportional to enzyme concentration when pure crystalline rennin is used, but varies as a power ($N < 1$) of the concentration for commercial

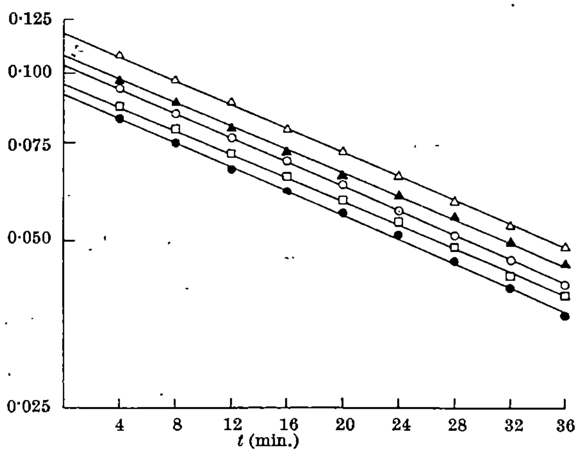

Fig. 1. Guggenheim curves for fall in viscosity of sodium caseinate from various milk sources: rennet A. △, Jersey; ▲, Friesian; □, Ayrshire; ○, bulk milk A; ●, bulk milk B

rennets. It seems likely that N reflects the purity of the rennet whereas k should give a measure of its activity. This latter may be high even for impure rennets, due to the presence of enzymes other than rennin. The problem is to find a reproducible substrate against which to compare different rennets, since milk, being a biological fluid, does not have a fixed composition; for example, milks may well differ in their proportions of κ-casein. The question is whether the composition of the κ-casein also varies.

We have found it possible to prepare sodium caseinates from milks not only from different herds but also from different breeds of cow, which give, within the limits of experimental error, the same value of k for any one rennet but, in general, different values for different rennets. These caseinates have the additional advantage that they show no appreciable aggregation.

The caseinate is prepared by finely precipitating it from fat-free milk at the isoelectric point (*p*H 4·7) with N hydrochloric acid, and then removing as much as possible of the soluble milk components by frequent washing and filtering. The acid casein is dissolved by the slow addition of 0·5 N sodium hydroxide, and vigorous stirring, taking care that the mixture does not become alkaline. Stirring is continued for at least 2 hr., with excessive acid casein present, before the concentrated sodium caseinate solution, which should now have a *p*H of 6·2–6·4, is filtered and freeze-dried. The experimental samples, made up from the freeze-dried sodium caseinate, are adjusted for *p*H and then heated to 80° C. for 5 min. to destroy the natural proteases. They are then kept for another 24 hr. in the cold to regain their normal viscosity, reduced during the heating. Before use it is also desirable to filter the substrate through suitable sinter-glass without suction. Unless these precautions are taken in preparing the caseinates, the values of k for different samples, using the same rennet, may differ considerably.

To determine k, a smooth curve is drawn by inspection through the graph of η_{sp}/time (where η_{sp} is the specific viscosity). There are normally some 20 points on each experimental curve. The time zero is the moment when rennet is added. Differences of η_{sp} ($\Delta\ \eta_{sp}$) corresponding to a standard time-interval ($\Delta\ t$) are determined, following Guggenheim's method[3]. The slopes of the Guggenheim curves, plotting log ($\Delta\ \eta_{sp}$) against t, give the values of k, only with a change of sign.

The positions of the curves would depend on the proportional falls in viscosity produced by the enzymes, that is, on the concentrations of κ-casein, except that, since viscosity does not vary linearly with caseinate concentration, an empirical adjustment is made to give the different samples approximately the same initial viscosities. Since the contribution of the products of decomposition of κ-casein to the total viscosity is not known, the proportion of κ-casein cannot be directly calculated, though it appears to be at least 20 per cent, and often more, that is, considerably higher than was previously supposed[1]. In Fig. 1 are shown a number of Guggenheim curves for sodium caseinates prepared from milks from different breeds and from mixed herds. It is clear that for some 50 min. at least, the reaction is very close to first-order. If the experiments are prolonged, the curves tend to deviate from linearity.

Table 1

Source of caseinate (cows' milk)	$k \times 10^4$ sec.$^{-1}$	
	Rennet A	Rennet B
Jersey	4·06	3·83
Ayrshire	4·01	3·87
Friesian	4·09	3·89
Bulk A	4·19	3·94
Bulk B	4·14	3·80
Bulk C	4·05	3·90
Bulk D	4·09	3·87
Mean	4·09	3·87
Standard deviation	0·0597	0·0458

In Table 1 are given values for k, together with their means and standard deviations, for caseinates from seven milks for two well-known brands of commercial rennet. Rennet A has a higher value of N and is known to be purer in rennin than is rennet B, but both are considered satisfactory for cheese manufacture.

We conclude that sodium caseinate, prepared as described, may be reproduced from milks from widely different sources and hence probably over long periods of time. The value of k for a particular rennet should thus provide a stable index of its activity.

A full account of this work, including details of experimental conditions, will be submitted, in due course, for publication (*J. Dairy Res.*).

We are indebted to our colleagues at the Institute for many helpful discussions.

Changes of Permeability of Yeast with Sodium Deoxycholate

Understanding of the phenomenon of cell permeability depends on detailed knowledge of the structure of the cell membrane. But the morphological and chemical organization of the cell membrane is still largely unknown. Study of the mechanism of action of detergents on the cell may represent one of

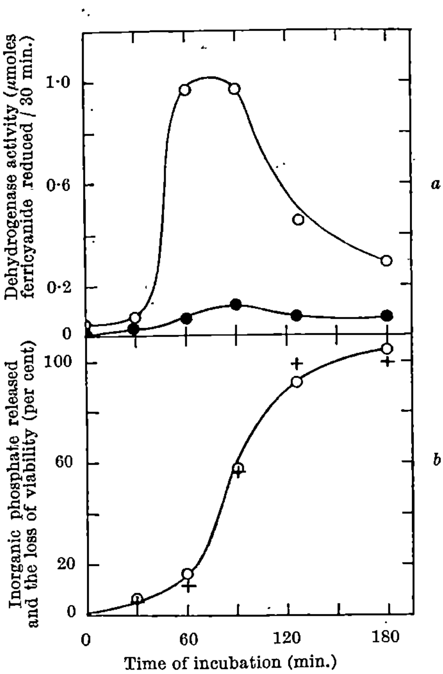

Fig. 1. Effect of deoxycholate on the dehydrogenase activity, inorganic phosphate released and viability in a suspension of yeast. Baker's yeast (11·7 mgm. dry weight/ml.) was incubated in 0·04 *M* *tris*-hydrochloric acid *p*H 7·5 with 0·006 *M* sodium deoxycholate at 27° C.; at suitable intervals, the medium was analysed for inorganic phosphate and the cells for succinic dehydrogenase activity. A portion of the cells was diluted and plated on Petri dishes with a synthetic medium; from the number of colonies the fraction of dead cells was calculated. *a* : ●, Dehydrogenase activity without added substrate; ○, succinic dehydrogenase activity; *b* : ○, inorganic phosphate released from the cells (per cent) (released by extraction with 10 per cent trichloracetic acid = 100 per cent); +, dead cells (percentage of total)

the suitable ways for the solving of this problem. From this point of view, the mechanism of action of deoxycholate on the yeast cell was investigated.

The intact yeast cells are not permeable to ions of dicarboxylic acids or to ferricyanide, hence no succinic dehydrogenase activity with ferricyanide as an electron acceptor can be demonstrated in the suspension of intact yeast cells. If deoxycholate is put into such a suspension, succinic dehydrogenase activity can be measured after a certain lag period; this means that in the presence of deoxycholate the cells become permeable. This effect of deoxycholate on the permeability is strongly dependent on temperature, increasing at higher temperature. The effect is enhanced by the lowering of *p*H (down to the point where the insoluble acid is precipitated) and by increasing ionic strength.

The dependence of the effect on the concentration of deoxycholate has a sigmoidal character. Under the experimental conditions used (see legend to Fig. 1), concentrations lower than 0·002 *M* were ineffective; at 0·005 *M* the effect was already maximal. At lower *p*H or higher ionic strength, the deoxycholate was effective even at lower concentrations.

Fig. 1 shows a time-course of the change in permeability of the cells incubated in the presence of deoxycholate, as measured by succinic dehydrogenase activity. The inorganic phosphate released from the cells and the viability of the cells are also plotted. Activity of succinic dehydrogenase reaches a maximum and then diminishes because of irreversible inactivation. Most striking is the fact that, while the loss of inorganic phosphate runs parallel to the loss of viability, which indicates that inorganic phosphate is released from the dead cells only, in a certain definite phase only about 20–30 per cent of cells are dead, while the succinic dehydrogenase activity measured is already a maximum. This suggests that part of the cells with the loose permeability barrier may be viable. This is supported, too, by the following observation: when the cells were pre-incubated with deoxycholate for such a time as to show almost a maximal or just a maximal succinic dehydrogenase activity and then washed with water, they did not show any, or only a very weak, succinic dehydrogenase activity, if deoxycholate were omitted from the test mixture. Thus, the action of deoxycholate may be, at least partly, reversible.

Recently, evidence has been provided by X-ray diffraction investigations[1], and direct observation by electron microscopy[2], that, under appropriate conditions, deoxycholate aggregates in solution to form a complex of macromolecular dimensions, the molecules assuming an elongated helical configuration. The dependence of the formation of these complexes on *p*H, on ionic strength and on the concentration of deoxycholate[3] is strikingly similar to the dependence of the changes of yeast permeability with deoxycholate on the above factors. This suggests strongly that the marked biological effect of deoxycholate, at least so far as its effect on yeast permeability is concerned, may be due to its ability to form helical fibre complexes. In these fibres, the hydrophobic steroid part of the molecule appears to be located inwardly, negatively charged carboxyl groups being on the surface. This seems to exclude the possibility that the molecules of deoxycholate would be oriented with their hydrophobic parts to the surface of the cell membrane and that the primary action of deoxycholate would be related to lowering of the surface tension. Rather there might exist another type of interaction, for example, similar to that which has been described recently by Lawrence[4], to explain the cleaning action of ionic detergents; that is, the interaction of the polar part of the deoxycholate complex with polar groups on the cell surface which would result in the formation of the ternary mixture, namely, polar part of deoxycholate/water/polar groups of the cell surface, followed by loosening of some components of the membrane, which are responsible for its permeability barrier.

CHEMISTRY

Discreteness-of-Charge Effect and the Stability Theory of Colloids

According to the stability theory of hydrophobic colloids of Derjaguin and Landau[1] and Verwey and Overbeek[2] (D.L.V.O. theory) the electrolyte concentration required to produce coagulation increases with the surface potential of the colloidal particles. However, for silver halide sols, the electrolyte concentration increases with surface potential for univalent flocculating ions, either decreases or remains approximately unchanged for divalent ions and decreases for trivalent ions[3,4]. This can be explained by incorporating into the D.L.V.O. theory the so-called discreteness-of-charge effect[5–8].

Using the electric double-layer model of Grahame[9] and Devanathan[10] for a plate-like particle, an 'inner region' of oriented water dipoles, of thickness $d(\sim 5$ Å.) and dielectric constant ε_1 ($\sim$10–20), is assumed to lie between the particle medium and the dispersion medium, of dielectric constants ε_p and ε ($\sim$80), respectively. The volume density in the dispersion medium of the potential-determining ions, which constitute the charge on the particle wall and are negative, is small compared with the corresponding density n of the coagulating electrolyte of a z-z valency type. A layer of cations, valency z, is absorbed on the inner Helmholtz plane (I.H.P.), inside the inner region at a distance $\beta < d$ from the plate wall. The outer Helmholtz plane (O.H.P.), at distance d from the wall, is the boundary between the inner region and the diffuse layer. The two zones of the inner region of thicknesses β and $\gamma = d - \beta$ act as condensers of capacities Kd/β and Kd/γ per unit area, where $K = \varepsilon_1/4\pi d$. The mean electrostatic potentials at the wall, the I.H.P. and the O.H.P., are denoted by ψ_0, ψ_β and ψ_d respectively. Also σ_0 and σ_β are the mean surface densities at the wall and the I.H.P. Then we have the relations: $\psi_0 - \psi_\beta = \beta\sigma_0/Kd$, $\psi_\beta - \psi_d = \gamma(\sigma_0 + \sigma_\beta)/Kd$, $\sigma_0 + \sigma_\beta + \sigma_d = 0$, where σ_d is the total charge in a column of the diffuse layer of unit cross-section. Applying the Gouy–Chapman theory to the diffuse layer:

$$\sigma_d = -\left(\frac{2n\varepsilon kT}{\pi}\right)^{1/2} \sinh\left(\frac{1}{2}\,\frac{ze\psi_d}{kT}\right)$$

where k, T and e have their usual meanings.

In the Stern theory of the double layer the energy of adsorption of the cation consists of a chemical term and an electrostatic term $ze\psi_\beta$ and the discrete nature of the ionic charge is ignored. In allowing for this effect, the Soviet authors[5,6,8] neglect the thermal motion of the adsorbed cations and replace the continuous charge distribution by a hexagonal array of discrete ionic charges. We adopt a simpler 'cut-off' approximation, suggested by Grahame[7], which is equivalent in principle. Each adsorbed cation is regarded as the centre of a circular area in the I.H.P. from which the uniform charge density σ_β is removed, of radius r_0 such that $\pi r_0^2\sigma_\beta = ze$. By considering the multiple electrostatic image reflexions in the plane of the plate wall and in the O.H.P., where the dielectric constant is discontinuous, the resulting change in the potential at the centre of the adsorbed cation can be expressed very nearly as:

$$\varphi_\beta = -\frac{\beta\gamma}{Kd^2}\,g\sigma_\beta$$

where g is a factor depending on ε, ε_1, ε_p and n. If $\varepsilon_1 \ll \varepsilon, \varepsilon_p$ then $g \approx 1$, but in general $g > 1$. The potential φ_β is a two-dimensional analogue of the self-atmosphere potential in the Debye–Hückel theory of electrolytes. The contribution $ze\varphi_\beta$ to the energy of adsorption is not small and is responsible for the apparent variation of the specific adsorption energy with surface charge at the mercury-aqueous electrolyte interface[9].

If each adsorbed ion, retaining a portion of its hydration shell, occupies s adsorption sites, then employing the volume fraction statistics of Flory[11] and Huggins[12], the Stern adsorption isotherm is modified to read:

$$kT\ln[\sigma_\beta/(1 - s\sigma_\beta/N_s ze)^s] = -ze(\psi_\beta + \varphi_\beta) + kT\ln n + C$$

where N_s is the number of adsorption sites per unit area and C is a constant which includes the chemical term in the adsorption energy. From these relationships maxima in both $|\psi_\beta|$ and $|\psi_d|$ are found at $\sigma_\beta = \sigma_\beta^{(m)}$, where:

$$\sigma_\beta^{(m)}[1 - s\sigma_\beta^{(m)}/N_s ze]/[1 + s(s-1)\sigma_\beta^{(m)}/N_s ze] = \frac{kT}{zeg}K\frac{d^2}{\beta\gamma}$$

The electrostatic work of adsorption of a cation is $-ze(\psi_\beta + \varphi_\beta)$, which increases steadily with plate potential. When the ratio $r = \sigma_\beta/\sigma_\beta^{(m)} < 1$, both $|\psi_\beta|$ and $|\psi_d|$ increase with $|\psi_0|$, but at larger coverages ($r > 1$) the variation of φ_β with ψ_0 predominates, causing $|\psi_\beta|$ and, therefore, $|\psi_d|$, to diminish. A maximum in $|\psi_d|$ was found experimentally at the mercury-electrolyte interface[13].

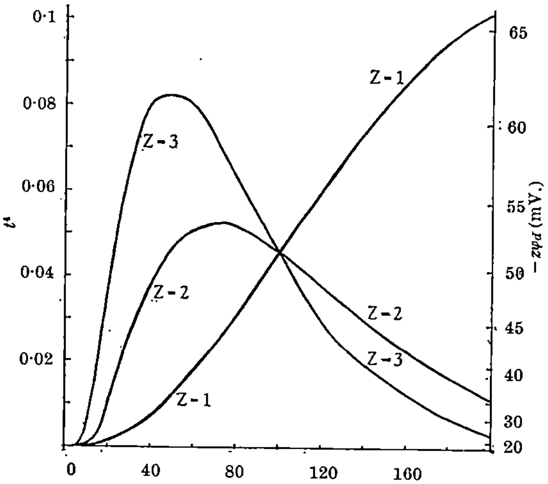

Fig. 1

Consider now two parallel plates of infinite thickness. If the potential distributions in the interpenetrating diffuse layers are linearly superposed, the coagulation condition becomes:

$$n = 107\,\frac{\varepsilon^3(kT)^5}{(ze)^6A^2}\,t^4,\quad t = \tanh\left(\frac{1}{4}\,\frac{ze\psi_d}{kT}\right)$$

where A is the constant in the van der Waals interaction energy. In the D.L.V.O. theory ψ_d is replaced by ψ_0 and, for large enough ψ_0, n is proportional to z^{-6}, a simple version of the Schulze–Hardy rule. In the typical plot of t^4 vs. ψ_0, by proper choice of C for $z = 1$, 2 and 3 this inverse sixth power rule is obeyed at $ze\psi_d/kT = 2$ and $r = 2$ for $z = 2$, where the three curves have a common intersection point ($\psi_d = 51{\cdot}4$ mV. if $z = 1$ and $T = 25°$ C.). Also $g = 1{\cdot}5$, $A = 2 \times 10^{-12}$ erg. cm.^{2}, $K = 30$ µF./cm.^{2}, $N_s = 5 \times 10^{14}$/cm.^{2}, $\gamma/d = 1/4$, $\varepsilon = 78{\cdot}5$ and $s = 1$, 3 and 5 respectively for $z = 1$, 2 and 3; the corresponding values of $\sigma_\beta^{(m)}$ are 2·84, 1·49 and 1·01 µcoul./cm.^{2}. The general trend of the dependence of coagulating concentration on plate potential is reproduced theoretically when $r < 1$ for $z = 1$, $r \gtrsim 1$ for $z = 2$ and $r > 1$ for $z = 3$.

Furthermore, deviations from the inverse sixth-power rule can occur, in agreement with experiment. The maximum in the $\psi_d - \psi_0$ curve, which is essential to the theory, is not obtained if the self-atmosphere potential φ_β is omitted. Various refinements, such as variation of K and γ/d with z and ψ_0 and a correction to the van der Waals energy due to the difference between the medium of the inner region and the particle medium, should not affect the general argument.

Part of the work by one of us (S. L.) was carried out at the National Research Council, Ottawa, Canada.

Permeation of Gaseous Oxygen through Vitreous Silica

THE permeation of gaseous oxygen through vitreous silica has been measured over the temperature-range 950°–1,080° C. in a permeation cell constructed with two portions separated by a thin-walled spherical bulb with a short neck. The bulb was 25 mm. outside diameter, and served as the membrane of vitreous silica ; its area was 18·9 cm.^{2} and thickness 0·27 mm. The thickness was determined from electrical capacitance measurements. The silica was used as blown ; and no cleaning was done with hydrofluoric acid. The oxygen pressure, 300–800 mm. mercury, was applied to the convex side of the bulb. The low-pressure side led directly to a mass spectrometer with no leak intervening. The rate of permeation of gas was measured[1], in this case by the peak height of mass 32. It was assured that true permeation, and not merely degassing, was being measured by : (1) observing the slow rise of the oxygen peak after application of oxygen to the high-pressure side, (2) attainment of steady-state flow and then, (3) slow decay of the peak after the gas was removed from the high-pressure side.

The experimental values of rate of permeation P on an Arrhenius-type plot of log P against $1/T$ yielded a good straight line, giving the results shown in Table 1. The units of P are those used by Barrer[2] ; cm.^{3} gas (S.T.P.) per sec. for 1 mm. thickness per cm.^{2} area per cm. mercury difference of gas pressure. From the slope of this plot an activation energy of permeation of 22,000 cal. per mole was derived.

The lag method of Daynes[3] and Barrer[2] is ideally adapted for the mass spectrometer to measure the rate of attainment of steady-state flow. By this method the diffusion constant D, in cm.^{2}/sec., was found to be $1·2 \times 10^{-8}$ at 1,078° C. and $4·2 \times 10^{-9}$ at 950° C., yielding diffusion activation energy of 27,000 cal. for oxygen in vitreous silica. The lag time at 950° C. for the steady state was slightly more than 8 hr. in this particular cell with a wall 0·27 mm. thick.

The solubility was derived from the relationship $S = 7·6\,P/D$, and found to be $1·9 \times 10^{-3}$ at 1,078° C. and $2·3 \times 10^{-3}$ at 950° C. The units are cm.^{3} gas (S.T.P.) per cm.^{3} solid for 76 cm. gas pressure applied.

The fact that molecular oxygen is the diffusing species is indicated by the observation that the rate of permeation was proportional to the first power of the pressure.

Table 1

Temperature (° C.)	Rate of permeation P
900	$9·00 \times 10^{-13}$
950	$1·25 \times 10^{-12}$
1,000	$1·85 \times 10^{-12}$
1,050	$2·50 \times 10^{-12}$
1,100	$3·50 \times 10^{-13}$

Aniline Oxidation initiated by Ultrasonic Waves

IN order to explain the chemical processes occurring in the ultrasonic field, Lindström and Lamm[1] assumed that the principal reaction occurring during the ultrasonic treatment of water is its decomposition into radicals:

$$H_2O = H + OH$$

By means of this reaction it is possible to explain a number of chemical processes[2–6], the oxidation of aniline included.

Aniline solutions (0·5, 1, 2 and 3 per cent, Merck) were used. All the solutions were prepared in redistilled water. The ultrasonic treatment was carried out in identical chemical vessels, containing 50 ml. of the desired aniline solution. A magnetostrictive transducer of 5·1 cm.^{2} radiation area was cooled by air in such a manner that the initial solution temperature (17°–18° C.) rose only by 4°–7° C., in accordance with the duration of the ultrasonic treatment. All the solutions were treated with the waves of 21-kc./sec. frequency and electric power of about 4·5 W./ml. of the solution.

All the aniline solutions of the appropriate concentration were treated with ultrasonic waves during 2 min. In the course of the treatment minute oxygen bubbles were let through every solution (about 35–40 bubbles per min.). After the treatment the solutions were poured into small calibrated cylinders with ground-in stoppers.

In the course of the observations it was found that the aqueous aniline solutions form different oxidation products after treatment as shown in Table 1.

Table 1

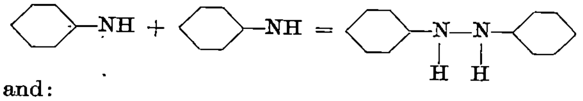
Aniline solution concentration (per cent)	Ultrasonic treatment duration	Colour of dye
0·5	2 min.	violet
1·0	,,	violet-blue
2·0	,,	orange
3·0	,,	black shot with green

The violet dye obtained does not change under the influence of hydrochloric acid. Potassium hydroxide solution changes the colour of the dye to brown, but after acidification with hydrochloric acid it regains its violet colour. The violet-blue dye showed no changes under the influence of 6 per cent hydrogen peroxide solution. It separates on a filter paper into two layers: an external one of violet colouring and an internal one of black colouring shot with green. Neither of the dyes, violet and violet-blue, has been identified, but it is possible that they are derivatives of *p*-benzoquinone of an undetermined structure.

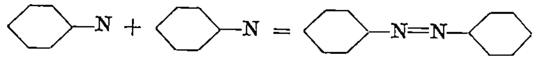
The orange dye has been identified as azobenzene, easily soluble in alcohol and especially in ether.

Concerning the azobenzene-forming mechanism in the ultrasonic field, it is necessary to assume first that aniline in aqueous solution decomposes into radicals:

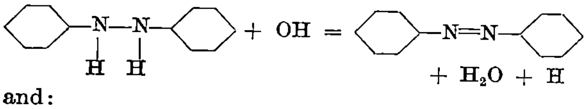
which, being in an unsaturated state, react with each other according to the equations:



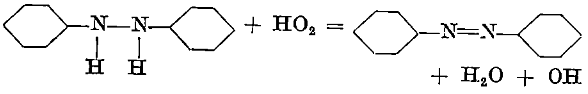
and:



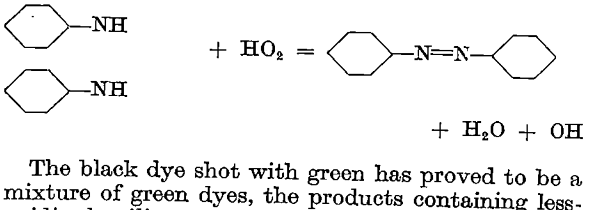
It is most probable that during the ultrasonic treatment of the aniline solutions in the presence of oxygen, hydrazobenzene is formed first, and is then readily oxidized by means of —OH or (OH_2) radicals, according to the equation:



and:



Reaction between the radicals is also possible, thus:



The black dye shot with green has proved to be a mixture of green dyes, the products containing less-oxidized aniline, and aniline black, not turning green when treated with hydrochloric acid.

The same quantities of the 3 per cent aniline solution were treated with ultrasonic waves during 1, 2, 3 and 4 min. respectively, at the temperature 17°–18° C. During the treatment, oxygen was let through the solution at the rate of about 35–40 bubbles per min.

In the course of the observations it was found that aqueous aniline solutions, during a short treatment (1–2 min.), formed mainly green products, probably emeraldine, nigraniline, and pernigraniline. After a longer treatment (3–4 min.) aniline black (not turning green) was mainly obtained as a polymolecular product containing numerous quinonoid bonds.

In the course of oxidation of aqueous aniline solutions it was found that an increase in the molecular pressure of oxygen did not lead to a rise in the oxidation effect.

Electron Affinity of the Acceptor Molecule in Charge-Transfer Complexes

Whereas the influence of the structure of the donor molecule in charge-transfer complexes on the stability and spectroscopic behaviour of these complexes has been investigated extensively, the role of the electron acceptor has been much less studied. One reason for this emphasis is the lack of measurements of a parameter related to the electron affinity of the acceptor molecule, in contrast to the fairly readily available ionization potentials of the donors.

It has been shown for alternant aromatic hydrocarbons that the one-electron polarographic half-wave potentials measured under conditions such that the mono-negative ions are virtually unprotonated are directly related to the energy of the lowest unoccupied molecular orbitals and hence the electron affinities of these molecules[1]. In general this may be expected to hold for any π-system, and the half-wave potential will at least be a measure of the readiness of the system to accept an electron[2].

A series of measurements has been carried out on well-known acceptors using acetonitrile and dimethylformamide as solvents; the polarographic characteristics of hydrocarbons and quinones are well established under these conditions[2]. The results given in Table 1 show the potential of the first one-electron addition ; in each case it was confirmed by a.c. polarography and conventional means that the electron addition is sufficiently rapid not to require a measurable over-voltage and that no proton addition occurs. These compounds show a second one-electron step, some 0·8 V. more negative than the first; for simplicity this has not been included in Table 1. The figures in Table 1 are, in general, clearly in the expected order for complexing ability[3,4], the stronger complexing agents having the more positive potentials. The results for the two solvents are practically identical. The difference in complexing ability between chloranil and quinone is well brought out in contrast with a comparison of their conventional redox potentials (689 and 700 mV.). This method would thus appear to be at least a useful means of comparing acceptor-strengths. An indication that the series may provide more than a qualitative comparison of acceptor strengths is provided in Fig. 1 in which the change in free energy for complex formation with pyrene, determined spectroscopically[4], is plotted against the polarographic half-wave

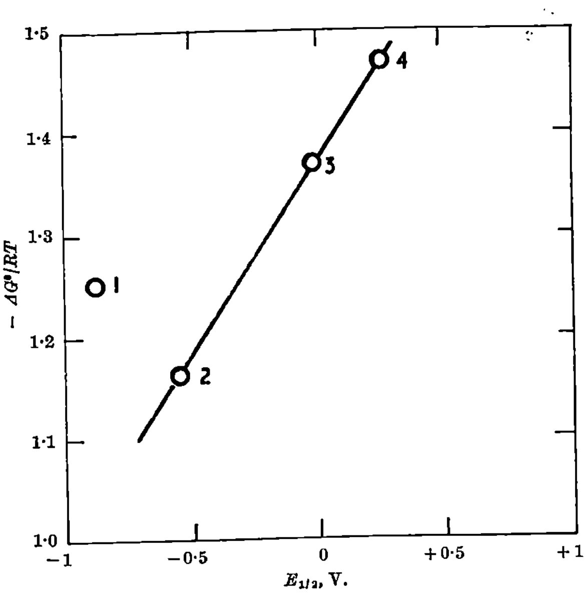

Fig. 1. Change in free energy of a series of complexes with pyrene (ref. 4) as a function of the half-wave potential of the acceptor. 1, Maleic anhydride; 2, *p*-benzoquinone; 3, chloranil; 4, tetracyanoethylene

potential of the acceptor. Other factors being equal, one would expect that the change in free energy would be directly related to the energy required to place an electron in the acceptor molecule. From Fig. 1 it would appear that the maleic anhydride complex has a greater stability than would be expected from the half-wave potential of this acceptor; pyromellitic dianhydride is also exceptional in this respect as it is claimed from spectroscopic measurements[5] that its complexing ability is close to that of tetracyanoethylene. An investigation into the reduction processes of anhydrides is in hand to see if further light can be thrown on this apparent anomaly.

The potentials of the second one-electron steps of the first three compounds in Table 1 lie at − 0·31, − 0·75 and − 0·80 V., in the region of the first steps for moderately strong acceptors. This suggests that it may be possible for a second electron to be shared with these molecules. This would apply more readily to compounds with even more positive half-wave potentials.

Further work is planned on the quantitative aspects of this approach to the problem of donor–acceptor complexes. If a quantitative correlation were established, it would provide a basis for a greater understanding of the factors contributing to the stability of the complexes. It would also appear feasible to investigate donor–acceptor equilibria by polarographic means in a manner analogous to that for metal-ion complexes[6] in which factors such as contact charge-transfer would not interfere.

Determination of Indium in High-purity Zinc

THE activation analysis of 5 parts in 10^{12} of indium in zinc has been carried out, using a method of separation investigated by Kosta and Hoste[1]. 1-gm. samples of zinc were irradiated in a neutron flux of 8×10^{11} n./cm.^{2} sec. in the *BR.I* reactor. After irradiation, the samples were dissolved in 10 ml. of 6 *N* hydrobromic acid with the addition of 3–4 drops of nitric acid (sp. grav. 1·40) in order to accelerate the dissolution. By addition of 5 ml. of 6 *N* hydrobromic acid to the solution, its concentration was increased to about 4 *N*. After two extractions with 5 ml. of isopropylether, the organic layer contained all the trivalent indium. Small amounts of zinc-65, which were present in the organic layer, were washed out with 10 ml. of 6 *N* hydrobromic acid.

The purified indium fraction contained the radioisotope indium-116*m* (*t*1/2 = 54 min.) and traces of zinc-65 (*t*1/2 = 240 days) and of zinc-69*m* (*t*1/2 = 14 hr.). Since discrimination of the gamma transitions of zinc-65 (E_γ = 1·114 MeV.) and of indium-116*m* (E_γ = 1·09 MeV.) is impossible by gamma-spectrometry, the activity of the former was determined by measurement of its 1·27-MeV. γ-ray. A single-channel gamma-spectrometer with a 3 in. × 3 in. sodium iodide (thallium) well-detector system was used for these measurements. The 438-keV. γ-ray from the isomeric transition of zinc-69 is used for measuring the purity of the indium fraction.

In order to avoid shadow effects of epithermal neutrons, the indium standards must be of very small size. Therefore one drop of an indium solution (0·2 mgm. indium/ml.) is weighed in a quartz tube and used as the standard. After irradiation and hundred-fold dilution, its level of activity is comparable to that of the indium in the samples. Results indicate the presence of 4·9–5·0 parts in 10^{12} of indium in three zinc samples of different purity in respect to other impurities.

Reactivity of Calcium Sulphate Hemihydrate

CALCIUM sulphate hemihydrate reacts with water to yield calcium sulphate dihydrate. The rate of this reaction differs considerably from sample to sample, the variations in reactivity being due, at least in part, to conditions prevailing during the dehydration of the parent dihydrate. We have investigated the reactivity of calcium sulphate hemihydrate prepared by calcining various samples of finely powdered reagent grade calcium sulphate dihydrate (44 per cent −100 mesh and +200 mesh, 54 per cent −200 mesh) spread as a thin layer (120 gm. per 500 cm.^{2}) on a tray in an air oven. After calcination the material was exposed to the atmosphere at room temperature to allow absorption of moisture until the composition of hemihydrate was attained[1]. The reactivity of the product was assessed from the rate of increase in temperature of mixtures of 100 gm. of hemihydrate with 60 gm. of water, held in a Dewar flask[2]. The mixtures were made at 20° C. Two parameters of the reaction were studied, namely, the induction period defined as the time taken for the rate of increase in temperature to exceed 0·1 deg. C./min., and k the slope of the approximately straight part of the plot against time of $\log_{10}\Delta T/\Delta T_f$, where ΔT deg. C. is the increase in temperature and ΔT_f is the increase in temperature corresponding to complete hydration. The constant k is a measure of the self-acceleration of the reaction[1-3]. The induction period is inversely related to the reactivity.

With the samples of calcium sulphate dihydrate which we have used the induction period of the derived hemihydrate has initially increased rapidly with the length of calcination and has finally become independent of it. With one particular sample calcined at 143° C. the induction period showed a pronounced maximum at 20 hr. (Fig. 1). With calcination of this sample at 203° C. the peak occurred at 5 hr., and at 106° C. there was no maximum in the induction period (that is, minimum in reactivity). There were corresponding but less-pronounced variations in k with length of calcination (Fig. 2). Similar changes in reactivity seem to occur when some samples of gypsum plaster are recalcined[1]. The induction periods for long times of calcination at 106° C. and 203° C. were considerably less than for calcination at 143° C. The magnitude of the increase in temperature during hydration showed that all the samples of calcined gypsum consisted essentially of calcium sulphate hemihydrate.

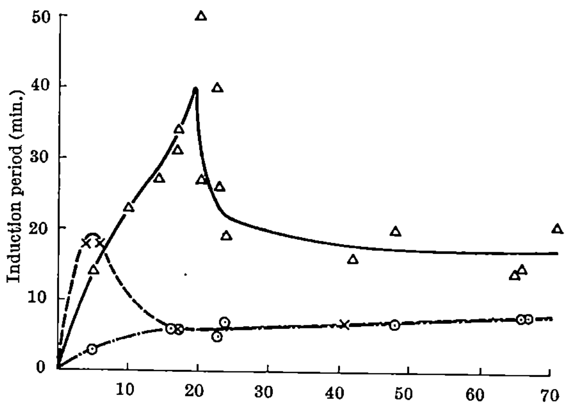

Fig. 1. Induction period plotted against period of calcination for samples prepared at 106° (⊙), 143° (△) and 206° C. (×)

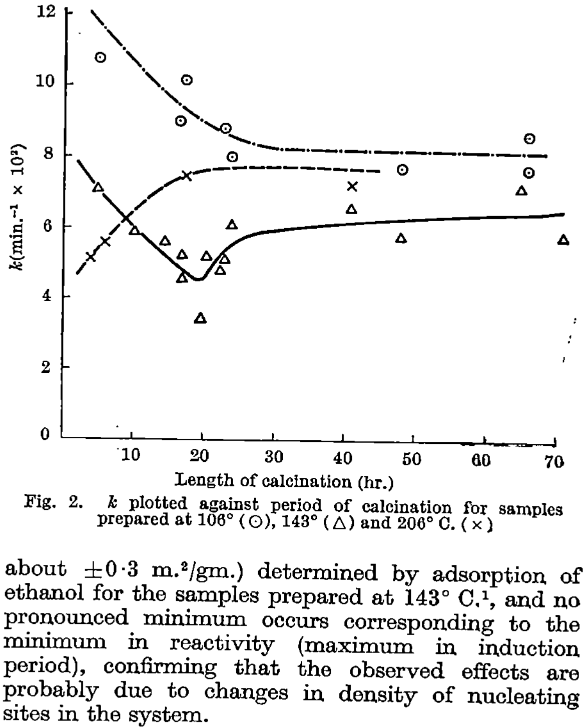

Fig. 2. k plotted against period of calcination for samples prepared at 106° (⊙), 143° (△) and 206° C. (×)

Variations in the reactivity of comparatively pure preparations of calcium sulphate hemihydrate, particularly when associated with sympathetic variations in k, are most likely to be due to differences in the density of seeding nuclei[1-3]. Large variations in surface area are reflected in the reactivity of calcium sulphate hemihydrate, particularly in the values of k[1]. However, Fig. 3 shows the surface area (error about ±0·3 m.^{2}/gm.) determined by adsorption of ethanol for the samples prepared at 143° C.[1], and no pronounced minimum occurs corresponding to the minimum in reactivity (maximum in induction period), confirming that the observed effects are probably due to changes in density of nucleating sites in the system.

The variations in reactivity described here can be explained by assuming the occurrence of two reactions that involve nuclei for the growth of calcium sulphate dihydrate. The first is the decomposition of the dihydrate lattice, and appears to be the only one occurring at 106° C. (Fig. 1). As calcination continues the product becomes less and less reactive as seeding particles of residual dihydrate disappear. As the temperature of calcination is raised this reaction becomes more rapid. However, there intervenes a

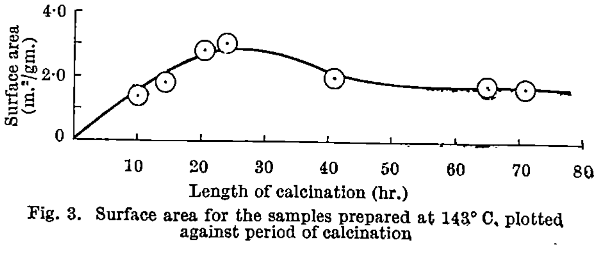

Fig. 3. Surface area for the samples prepared at 143° C. plotted against period of calcination

second reaction (presumably with a higher activation energy) that produces new nuclei so that at higher temperatures the reactivity first falls and then increases again. The nuclei produced by the second reaction are most unlikely to consist of fragments of dihydrate lattice, and the reaction probably involves some type of re-arrangement of the surfaces of the particles. The values of the surface area show no large variations, but the slight variations shown by the values for samples prepared at 143° C. may suggest a type of slow sintering after 20 hr. (Fig. 3). If the new sites favourable for nucleation of dihydrate do result from a re-arrangement of the surface of the grains of hemihydrate, they must be due to geometric features rather than to regions of strain.

The behaviour of some other samples where the peak is absent is due to the rates of these reactions, particularly the second, being so fast that the peak occurs so early that it is lost in the drop of reactivity caused by the first reaction. That an inhibitor which disappears at higher temperatures is not responsible for the effects described in this communication is indicated by the comparatively high reactivity of the samples prepared at 106° C.

BIOCHEMISTRY

Prevention of Ammonia Toxicity by Amino-acids concerned in the Biosynthesis of Urea

Relationships have been pointed out by several investigators[1] between high levels of blood ammonia and various clinical syndromes, for example, some psychoses, mental disturbances associated with heart failure, tumours, jaundices, hepatic encephalopathies, etc. In some cases a reduction in the level of ammonia has resulted in considerable amelioration of these pathological symptoms; the various procedures for this purpose are of considerable interest[1].

In 1956, Greenstein and co-workers[2] emphasized the antitoxic action of L-arginine in experimental hyperammonæmia produced by intraperitoneal injections of ammonium salts or high amounts of certain amino-acids. This work was followed by clinical studies, and some investigators[3] obtained beneficial results after administration of L-arginine; in all these cases the authors observed a striking reduction of blood ammonia which paralleled the alleviation of toxic symptomatology.

Different procedures for the same purpose have been employed with as yet indecisive results[1,4]. While the action of glutamic acid might be due to removal of the toxic ammonia via glutamine synthesis, the effect of L-arginine may involve a mobilization or enhancement of the Krebs–Henseleit urea-synthesizing cycle, resulting in a decrease of the ammonia-level; this hypothesis is supported by the observation of appreciable increases in the levels of blood urea[2,3].

Table 1. Effect of Prior Administration of Amino-acids on Rats given LD_{50} Doses of Ammonium Acetate

Protective compounds	Dose (m.moles/kgm.)	No. of animals	Survivors (per cent)	Incidence of convulsion (per cent)
Phosphate buffer	—	25	48	100
L-Ornithine + L-Aspartic acid	0·5 0·5	20	95	20
L-Ornithine + L-Aspartic acid	1·0 1·0	25	100	0
L-Ornithine + L-Aspartic acid	1·5 1·5	20	100	0
L-Ornithine	3·0	20	100	0
L-Aspartic acid	3·0	19	58	85
L-Aspartic acid + L-Ornithine	2·5 0·5	31	90	20
L-Lysine	3·0	10	50	100
L-Isoleucine	3·0	17	65	88
L-Isoleucine + L-Ornithine	2·5 0·5	27	63	80
L-Ornithine	0·5	32	93	43

The animals were Long–Evans male rats weighing about 250 gm., starved for a period of 12 hr. with water *ad libitum*. Both ammonium acetate and amino-acids dissolved in phosphate buffer (final *p*H 7·4), were administered intraperitoneally; the amino-acids 1 hr. before ammonium salt. Control animals were treated only with phosphate buffer before the ammonium acetate.

We have tested other substances concerned in the synthesis of urea for a similar effect. For this, some amino-acids, mainly L-ornithine and L-aspartic acid, have been tested in chronic carbon tetrachloride poisoning in rats[5]; their protective efficiency was evaluated on the bases of increase in weight and of the total lipid and glycogen content of the livers; the efficiency reaches 96 per cent if an ornithine–aspartic acid mixture (2·5 m.moles/kgm.) is used. The present communication describes the protective effects of prior administration of this mixture against experimental hyperammonæmia produced by intraperitoneal injection of LD_{50} quantities of ammonium acetate (8·2 ± 0·8 m.moles/kgm.) into rats.

The first set of experiments established the protective effects of some amino-acids against the mortality of rats suffering from ammonia intoxication (Table 1). The mixture of L-ornithine and L-aspartic acid, after intraperitoneal administration, gives optimum protection at levels of 2·0 m.moles/kgm. body-weight; at levels of 1·0 m.mole/kgm., 95 per cent of the animals survived. It is noteworthy that aspartic acid alone (3·0 m.moles/kgm.) has almost no effect, whereas the addition of ornithine in rather low concentration (0·5 m.mole/kgm.) suffices to raise the survival-rate to 90 per cent. We have also tested other amino-acids which are not involved in the synthesis of hepatic urea. L-Lysine alone (3·0 m.moles/kgm.) is completely inefficient, whereas L-isoleucine shows a protective effect slightly greater than that shown by aspartic acid alone; the addition of L-ornithine does not produce any increase of efficiency.

Levels of ammonia and urea in the blood of these animals were determined after various protective treatments (Table 2). In protected rats the rise of blood ammonia was quickly checked and, in animals treated with the ornithine–aspartic acid mixture (1·5 m.moles/kgm. of each), the values fell rapidly to normal levels. Simultaneously, the levels of blood-urea showed a marked increase.

These results suggest that ornithine and aspartic acid exhibit a specific detoxifying action toward

Table 2. Ammonia- and Urea-Levels in Blood of Rats protected against LD_{50} Doses of Ammonium Acetate by the Prior Administration of Mixtures of L-Ornithine and L-Aspartic Acid

No. of animals	Ammonium acetate	Protective mixture	Dose (m.moles/kgm.)	Blood ammonia (μmoles/ml.)		Plasma urea (μmoles/ml.)	
				Time after injection of ammonium-acetate (min.)			
				15	60	15	60
50	—	Phosphate buffer		0·76 ± 0·11*	0·76 ± 0·11	5·98 ± 0·73	5·98 ± 0·73
30	—	L-Ornithine + L-Aspartic acid	1·5 1·5	0·96 ± 0·12	0·71 ± 0·11	7·11 ± 0·54	7·81 ± 0·69
50	LD_{50}	Phosphate buffer		6·28 ± 0·33	2·59 ± 0·52	7·45 ± 0·76	9·87 ± 0·76
40	LD_{50}	L-Ornithine + L-Aspartic acid	0·5 0·5	3·77 ± 0·71	1·72 ± 0·72	7·66 ± 0·53	10·42 ± 1·34
50	LD_{50}	L-Ornithine + L-Aspartic acid	1·0 1·0	2·19 ± 0·39	1·39 ± 0·35	9·83 ± 0·90	12·76 ± 1·89
40	LD_{50}	L-Ornithine + L-Aspartic acid	1·5 1·5	2·38 ± 0·34	0·64 ± 0·39	10·53 ± 0·68	14·71 ± 1·81

The experimental conditions were as given in Table 1. Blood samples were drawn by cardiac puncture at the times indicated; the time of 15 min. was selected to coincide with the death of 50 per cent of the intoxicated animals. The survivors of this group were examined along with the other animals after 1 hr. Ammonia was determined in whole blood by Seligson's method (ref. 6); urea was determined in plasma by Kitamura's method (ref. 7).

* Mean values ± standard deviations.

blood ammonia. Their effect may be attributed to an enhancement of the Krebs–Henseleit mechanism of synthesis of urea.

The results of a more detailed investigation in progress will be published elsewhere.

Chemistry of a Mucopolysaccharide produced by Guinea Pig Lymphocytes

The guinea pig lymphocyte has long been known to contain a special inclusion body. Such lymphocytes, called Kurloff cells after their discoverer, increase greatly in number in pregnancy and were shown by Ledingham[1] to be produced in both males and females by administration of œstrogens. Marshall and Swettenham[2], by histochemical methods, have shown that the inclusion body is composed of a mucoprotein–sulphated mucopolysaccharide complex. Further work on the chemistry of a mucopolysaccharide fraction by extraction of spleens of œstrogen-treated guinea pigs gave the following results:

(1) No linked amino-acids are present in the polysaccharide fraction; (2) the electrophoretic mobility in phosphate buffer at *p*H 7 on cellulose acetate is the same as chondroitin sulphate; (3) the bulk of the amino-sugar is composed of galactosamine (Gardell's method[3]); (4) the molar ratio of hexosamine, uronic acid and sulphate is the same as chondroitin sulphate *A* or *C*, that is, if hexosamine = 1 (sulphate = 1·29, uronic acid = 1·43 and sodium = 3·43); (5) the material is susceptible to testicular hyaluronidase. Some of the technical methods used in these estimations will be described later in a separate publication.

These results confirm the conclusion of Marshall and Swettenham[2] that the inclusion body of the Kurloff cell contains a material similar to the ground-substance of cartilage or connective tissue. The formation of large amounts of such material in the pregnant animal, however, remains of unknown significance and attempts to trace the fate of this polysaccharide in the pregnant guinea pig by labelling with sulphur-35 were unsuccessful. Furthermore, it is uncertain whether the formation of such material is peculiar to guinea pig lymphocytes or whether it is only the formation of the inclusion body which is unique to this species.

Influence of Plasma Proteins in the Control of Mitosis-rates in Generating Liver

Many experiments have been done to elucidate mechanisms of control over growth-rates of liver, and in a comprehensive review of the regenerating liver Harkness[1] suggests that variations in the levels of plasma proteins, as shown by Glinos[2] and Gey[3], offer the most likely cause of changes in mitosis-rates after partial hepatectomy. Lately new evidence in favour of the removal of a normally present inhibitor has been offered from mouse skin[4] and from rat and guinea pig liver[5].

It was shown that adrenal corticosteroids could be the inhibitor normally present[5,6], and I now suggest control of mitoses in at least two ways: First, by a change in concentration of the plasma corticosteroids as shown by several workers[6–8] and to which normal cells are sensitive. Secondly, by a possible alteration of redox potential around each cell which has the effect of preventing corticosteroid influence on mitosis[5]. This effect has been shown by withdrawal of ascorbic acid from guinea pigs, but similar conditions could result from the output of oxidizing substances from damaged cells, such as tumours, or in wound healing where the levels of circulating corticosteroid may be high yet mitosis-rates are not inhibited.

In the experiments of Glinos[2] alterations are made in the concentrations of plasma proteins believed to control mitosis; he demonstrates induction of mitosis in resting liver by dilution of plasma proteins and conversely a suppression of mitosis in regenerating liver by hæmo-concentration following water restriction.

Plasma proteins have been shown to carry corticosteroids[9,10], and it seems likely that the plasma protein influence is attributable, at least in part, to the associated corticosteroids; changes of protein-levels automatically altering the corticosteroid inhibition. To test this, Glinos's hæmo-concentration experiment has been repeated, but a comparison has been made between the degree of inhibition of liver regeneration in a dehydrated rat with intact adrenals and one with adrenals removed. If corticosteroids were the effective controllers of mitosis, adrenalectomy would allow a high rate of liver regeneration approximately double that found in rats with intact adrenals[5]. This has been demonstrated, even though plasma protein-levels have been maintained near those found in intact rats, which have no liver mitoses in a resting state.

Three groups of Wistar male rats weighing 200 gm. were compared. The first group of 60 rats were adrenalectomized and given food *ad lib.* but no water: 24 hr. later partial hepatectomy was done and the liver allowed to regenerate for 28 hr., when the rats were killed and a slice of the growing liver remnant taken for mitotic counting. The rats were bled by withdrawal of blood from the inferior vena cava and plasma protein estimated by the copper sulphate specific gravity drop method. Total time deprived of water was 52 hr.

The second group of 30 rats with intact adrenals were partially hepatectomized after deprivation of water for 24 hr. and were killed after 28-hr. liver regeneration, water being withheld also for a total of 52 hr. The third group of 10 rats with intact adrenals were given food and water *ad lib.* and partially hepatectomized. After 28 hr. liver regeneration the rats were killed and liver slices and blood collected for examination as in the preceding groups.

Mitotic counts of regenerated liver and plasma protein-levels are shown in Table 1 (mitoses per 1,000 cells).

Table 1. PLASMA PROTEIN AND MITOTIC COUNTS OF RAT LIVER REGROWING 28 HR. AFTER PARTIAL HEPATECTOMY

	Group 1	Group 2	Group 3
	Dehydrated adrenalectomized rats	Dehydrated intact adrenals (gm.)	Water allowed, adrenals intact (gm.)
Plasma protein (gm.) (per cent)	7·9 ± 1·3	9·1 ± 1·1	5·9 ± 0·8
Mitotic rate	62 ± 8	16 ± 5	38 ± 6

(± *S.D.*)

In group 1 the adrenalectomized dehydrated rats showed a higher liver regeneration-rate almost double that of the intact hepatectomized rats having full access to water which formed the third group. In the former case plasma protein concentration has been maintained but absence of corticosteroids has removed all inhibition on mitosis.

Groups of dehydrated rats with intact adrenals show an inhibition of mitosis in the regenerating liver as reported by Glinos. Here plasma protein-levels have been maintained and in addition it is likely that corticosteroid output is high due to the stress of water deprivation.

The third group shows the plasma protein and mitotic rates in partially hepatectomized rats not deprived of water. Plasma protein-levels of intact rats average 8–9 gm. per cent.

It appears, therefore, that plasma proteins are only partly responsible for mitosis regulation in liver, and that they form a vehicle for the carriage of corticosteroids which are the effective control. The reasoning of Glinos is not invalidated by this extension as the homeostatic mechanism of maintenance of plasma proteins carries with it a built-in control, the cortical hormones, which only achieve an inhibiting effect on liver growth when this organ is of a size sufficient to maintain full plasma protein-levels and thereby a proper concentration of corticosteroids.

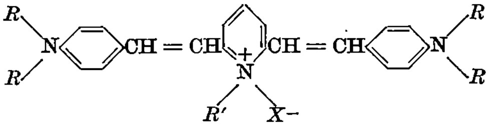
Pyridine Derivatives with Anthelmintic Activity

WE should like to report a new series of chemical compounds which are effective against certain nematode parasites of mammals. Some of these compounds show a broad anthelmintic spectrum, being active against representatives of a number of families of nematodes.

These compounds can be illustrated by the general structural formula (I):



(I)

in which R can be, for example, alkyl or benzyl, or  can consist of a cyclic ring, such as pyrrolidine, piperidine, morpholine, etc., and R' can be alkyl or benzyl and X^- can be a suitable anion, most commonly iodide. These and numerous other structural variations have been prepared and tested, and details of syntheses will be published shortly.

A number of members of this series were found quite active against natural infections of the mouse pinworm, *Syphacia obvelata*, but two of the series (A: (I) $R = CH_3$, $R' = CH_3$, $X = I$; (I) $R,R = (CH_2)_4$, $R' = C_2H_5$, $X = I$) gave superior and almost equal activity with single doses of as low as 5 mgm. of base per kgm. of body-weight. Although B was slightly better against *Syphacia*, it was less effective than A against various nematodes of dogs and cats.

Compound *A* was tested extensively against nematodes of dogs and cats, and, to a limited extent, against nematodes of monkeys, using single doses of 25 mgm./kgm. or less for most parasites or multiple doses of 25 mgm./kgm. for whipworm infections. It exhibited a broad anthelmintic spectrum, showing good to excellent activity against natural infections of *Ancylostoma caninum*, *Toxocara canis* and *T. cati* in dogs and cats; *Uncinaria stenocephala*, *Toxascaris leonina* and *Trichuris vulpis* in dogs; and *Trichuris trichiura*, *Oesophagostomum apiostomum* and *Physaloptera* sp. in monkeys.

Inasmuch as rats, dogs and cats have tolerated single doses as large as 500 mgm. per kgm. of body-weight without evidence of ill effects, there is a wide margin of safety between the effective and toxic doses and, in addition, the compounds are tasteless and appear to have negligible emetic activity.

Comparison of the Serum Protein Fractions of the Newly Hatched Chick with those of Adult Birds using Starch-gel Electrophoresis

It has been established by several investigators that serum protein components of chick embryo undergo qualitative as well as quantitative changes throughout the developmental period until the time of hatching[1-4]. The serum protein composition of the newly hatched chick, however, resembles that of the adult bird, as revealed by moving-boundary and paper electrophoresis. The technique of starch-gel electrophoresis suggested by Smithies[5] is promising in that it enables one to detect numerous fractions in the pattern of the serum proteins, particularly in the α- and β-globulin regions, which cannot be detected by the conventional method of Tiselius or paper electrophoresis. By using the starch-gel method, I have been able to demonstrate differences in the patterns of serum proteins of the day-old and week-old chicks when compared with pooled sera of one- and two-year-old roosters, as shown in Fig. 1. The electrophoresis was performed on a vertical tray[6] for 18 hr. using borate buffer of *p*H 8·6 and a field-strength of 6 V./cm. Repeated electrophoretic runs gave patterns similar to those shown in Fig. 1, for the four age groups. Twelve fractions could be distinguished on the patterns of the adult roosters (two pre-albumin components are not seen on the photographs). The same number of fractions could also be seen on the electrophoretic patterns of the young chicks. The mobility and the number of fractions of α-globulins of the newly hatched chicks are distinctly different from those of adult birds. The fraction *b* of the serum of a day-old chick does not seem to be present in the serum of an adult bird, and of fraction *d* only traces are observed. Very little γ-globulin is present in day-old and week-old chicks. A distinct narrow band which is immediately behind the albumin (a post-albumin ?) in the adult bird cannot be seen in the young chicks.

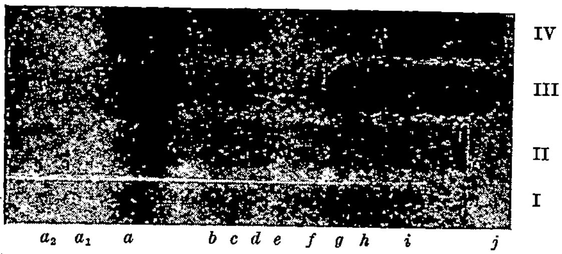

Fig. 1. Starch-gel electrophoresis of the sera of chicken at various ages. I, Day-old chick; II, week-old chick; III, one-year-old rooster; IV, two-year-old rooster

Cholesterol in the Tapetum Lucidum of the Eye of the Opossum, *Didelphis virginiana*

The eye of the opossum *Didelphis virginiana* has a tapetum formed from the retinal pigment epithelium[1,2]. Investigation of the eyes of three specimens of *Didelphis virginiana* and of one specimen of the crab-eating opossum obtained through the kindness of Dr. S. Halbert, College of Physicians and Surgeons, New York, and of Dr. Osman Hill, Zoological Gardens, London, has shown that the tapetum of these animals is rich in cholesterol, cholesterol esters and lipids and it is tentatively suggested that these form the reflecting material *in vivo*.

The tapetum of the opossum, viewed ophthalmoscopically immediately after death, appeared as a triangular dead-white area. Dissection of the tapetal area was unsatisfactory, both in unfixed and in eyes fixed with formol, as it was difficult to separate it from overlying retina and underlying choroid. The roughly separated tapetum was dried, extracted with chloroform–methanol 1 : 1 (v/v), and both extract and residue were examined. Microscopical examination of the residual material showed that birefringence of the tapetum had been removed. The chloroform–methanol extract was dried and the residue extracted with acetone. The acetone-soluble fraction consisted largely of cholesterol as judged by estimation[3]. Paper partition chromatography[4], using 95 per cent methanol as solvent, showed that cholesterol esters and/or fat were present as well as free cholesterol. In this system cholesterol esters and fat remain at the origin and cholesterol has R_F 0·50. Markers of cholesterol, cholesterol oleate and cholesterol stearate were run in parallel. To determine whether the material in the tapetum which remained at the origin on the chromatogram contained cholesterol esters or was entirely fat, an aliquot was saponified and re-chromatographed alongside the original material. The spot at the origin disappeared on saponification and the spot corresponding to cholesterol became more intense and larger, which suggests that cholesterol esters are present.

One eye was examined histologically. After fixation with formol, the eye was opened and the lens, which is large and spherical, was removed. The back part of the eye was then embedded in gelatin and frozen-sections were cut and floated on gelatin-coated slides. When the Lieberman–Burchardt reagent was dropped on the sections, a strong positive cholesterol reaction developed in the area of the tapetum, and a weaker one was given by the optic nerve. Retina and choroid were negative. Staining with sudan III showed that the tapetal area was also rich in lipid. A few lipid globules were present in the choroid and orbital tissues.

These experiments showed that the opossum tapetum contained cholesterol, cholesterol esters and lipid, and that when these were extracted the birefringence of the original material was lost. An attempt was therefore made to estimate the total cholesterol of the different parts, dissected from a single eye of *Didelphis virgiana* (Table 1).

Table 1. CHOLESTEROL CONTENT OF DIFFERENT PARTS OF THE EYE OF *Didelphis virginiana*

Part of eye	Dry weight (mgm.)	Total cholesterol (per cent dry weight)
Sclera	84	0·4
Choroid	7·3	5·8
Retina	2·8	18·2
Tapetum	1·0	50·0

Table 1 shows that the dissected tapetum is richer in cholesterol than the other parts. Chromatography of this material before and after saponification showed that the cholesterol was largely esterified. It is probable that most of the cholesterol found in the dissected retina and choroid comes from contaminating tapetal tissue. Cattle retina contains only 2·0 per cent cholesterol and cattle choroid 0·80 per cent[5].

Roughly dissected tapetum from the unfixed eye was birefringent but crystals were not clearly detected. Crystals (Fig. 1) could be brushed off the tapetum of the eye fixed with formol and similar crystals were deposited from the chloroform–methanol and subsequent acetone extract of tapetal material. The appearance of the tapetum seen ophthalmoscopically or in the opened eye is chalk-white, without the brilliance which one sees from the crystals of guanine in the argentea and tapetum of fish. There is no iridescence.

Different animals solve the optical problem of providing a mirror backing to the retina in widely different chemical ways. The crystalline tapetum in fish and reptiles is made of guanine[6], in carnivores of zinc-cysteine[7,8], in lemurs of riboflavin[9], and in the opossum of cholesterol esters and lipid. In fish, guanine is also laid down in the scales, and in lemurs Dr. Osman Hill (personal communication) has detected large amounts of a yellow water-soluble pigment in the skin, which is probably riboflavin. Whether zinc-cysteine occurs in other tissues of carnivores and whether there is particular concentration of cholesterol and lipid in other organs in the opossum are not known.

PHYSIOLOGY

Localization of the 'Sugar Pump' in the Intestinal Epithelium

GLUCOSE is actively transported across the intestinal epithelium from the lumen of the gut into the blood *in vivo* or into the fluid surrounding the serosal mesothelium *in vitro*. Because part of the glucose is metabolized during transport, it is not possible to determine the concentration of the unaltered sugar in the various layers of the intestine. However, 3-O-methylglucose, though transported by the same mechanism which acts on glucose[1], is not metabolized in animal tissue[2,3]. The synthesis of 3-O-$^{14}CH_3$-glucose in this laboratory[3] offered a method of following with reasonable accuracy the route of this sugar during transport.

Using surviving preparations of the small intestine of frogs (*Rana pipiens*), the following experimental procedure was employed[4]. 3-O-methylglucose (mixed with 3-O-$^{14}CH_3$-glucose) was dissolved in a Ringer's solution isosmotic with frog's blood and containing sulphate instead of chloride in order to minimize net water transport. The frogs were pithed, the abdomen was opened and the small intestine was ligated at both ends and injected with 1 ml. of the 3-methylglucose solution. The intestine was then excised and transferred to a flask containing 2 ml. of the solution identical with that which was injected into the lumen of the gut. The preparation was briefly gassed with a mixture or 95 per cent oxygen plus 5 per cent carbon dioxide and shaken in a 30° water-bath for 6 hr. Then the intestine was removed, carefully blotted on the outside and emptied of its contents. Thereafter, the intestine was split open, the mucosal surface gently blotted with a piece of cotton and the mucosa scraped off, using a coverglass. The mucosal scrapings were weighed, placed in a test-tube containing a known volume of hot water and refluxed in a hot water-bath for 10 min. The remaining portion of the intestinal tissue ('submucosal tissue') was similarly weighed and extracted with boiling distilled water.

Thus, at the end of the experiment, there were four different solutions : the contents of the lumen

Table 1. DISTRIBUTION OF 3-O-$^{14}CH_3$-GLUCOSE IN THE SMALL INTESTINE OF THE FROG

Exp. No.	Initial 3-methylglucose		Distribution of radioactivity at 6 hr. 10^3 counts/min./ml.			
	m.mol./litre	10^3 counts/min./ml.	Inside	Mucosal	Sub-mucosal	Outside
1	10	20·00	3·96	19·41	21·52	24·29
2	10	20·00	7·68	19·41	24·14	22·08
3	10	20·00	6·14	21·48	23·00	24·96
		Average	5·79	20·10	22·89	23·78
4	2·5	20·00	6·63	17·10	22·47	21·54
5	2·5	20·00	9·93	14·95	18·22	17·03
6	2·5	20·00	4·85	18·19	19·39	16·98
		Average	7·14	16·75	20·03	18·52

('inside fluid'), the extract of the mucosal scraping, the extract of the submucosal tissue, and the 'outside fluid' bathing the serosal mesothelium. From each solution samples were plated on to planchets and the radioactivity was counted in a windowless flow counter. The results were corrected for self-absorption. The water content of the tissue samples was calculated on the basis of an average value obtained in a series of determinations on both mucosal scrapings and submucosal tissues. The activity was expressed as counts/min./ml. of tissue water and of inside and outside fluids.

The results are shown in Table 1. The two series of experiments differ only in the initial concentration of 3-methylglucose; the amount of the tracer was the same in both series. As the principal anion was sulphate, which in turn kept the net movement of water across the intestine to a minimum, the change in concentration of the tracer in any compartment reflects the actual movement of 3-methylglucose regardless of its original concentration. It is evident from the results in Table 1 that during the experiment the concentration of 3-methylglucose decreased considerably in the lumen of the intestine, and that the concentration of 3-methylglucose in the water of the mucosal epithelial cells increased to a level two to three times higher than that in the lumen of the gut. The differences in concentration of 3-methylglucose between the other layers of the intestine and the serosal compartment are not so striking, and it is questionable if they were of any significance.

These results would suggest the following hypothesis: membrane facing the lumen of the intestinal epithelium is relatively impermeable to the sugar, and it is the site of the active transporting 'pump'. This would allow the sugar to be transported into the cell against a gradient and at the same time prevent a retrograde movement out of the cell into the lumen. The serosal-facing membrane of the epithelial cell is relatively permeable to sugar and so are the other tissues lying between the epithelial cells and the free serosal compartment. Thus, no appreciable concentration changes occur across these barriers.

These experiments do not indicate directly whether or not 3-methylglucose is present in the mucosal epithelial cells in the free or bound form. The concentration of 3-methylglucose is almost identical in the epithelial layer and in the subepithelial tissue as well as in the serosal compartment. If part of the sugar were bound in the mucosal cells, one would have to assume that a second concentration gradient of free sugar across the serosal-facing membrane occurred.

Attempts to demonstrate the presence of protein-bound 3-methylglucose in the extracts of intestinal mucosal epithelium were not successful. In these experiments the mucosal scrapings of 3-O-$^{14}CH_3$-glucose-absorbing guts were extracted with either cold saline or cold 0·6 *M* potassium chloride. Both extracts were centrifuged at 100,000*g* for 8 hr. More than 90 per cent of the total nitrogen of the extract was in the sediment, but the radioactivity in the supernatant did not change.

Increase in Elastin Content of the Human Aorta during Growth

It is generally assumed that the elastic properties of the gross arteries, such as the aorta, are essentially due to elastic fibres of the arterial wall. However, there are few reports of quantitative studies of elastin in aorta; and often statistical proof of significance is omitted and conflicting statements have resulted. In particular, more detailed investigations on the elastin behaviour of the human aorta during growth are required.

Smith *et al.*[1] referred to increases in elastic tissues of the media with ageing, whereas no variation of the elastin content was found by Hass[2] or by Lansing *et al.*[3]. In agreement with the considerable decrease of elasticity of the aorta observed in ageing, Myers and Lang[4], Faber and Møller-Hou[5] and Bertolin[6] reported elastin as being highest in early life and gradually declining in the last decades of life. Kraemer and Miller[7], however, the only authors who reported statistical analysis of their own results, demonstrated an absence of changes with age in the percentage of aortic elastin.

All methods hitherto used in the determination of elastin consist basically of destroying materials other than elastin and gravimetric determination of the remaining insoluble substance. The availability of a new and specific method that permits the direct colorimetric estimation of elastin without destructive processes led me to review the behaviour of elastin in human aorta during growth and ageing.

This preliminary communication discusses the results of work on 16 normal young subjects up to 20 years old.

The direct method previously described by me[8], later further improved[9], has been used. The sample of tissue is treated with orcein. All free stain is removed and the stained orcein-elastin compound hydrolysed with elastase (pancreatin). Orcein-elastin, which is brought in this way into solution, is then estimated photometrically.

Fresh specimens were removed at the time of autopsy from the aortæ of apparently normal male subjects between 0 and 20 years of age who died from trauma. Specimens free from atherosclerotic lesions were always taken from the inferior part of thoracic aorta, stripped of adventitia and treated

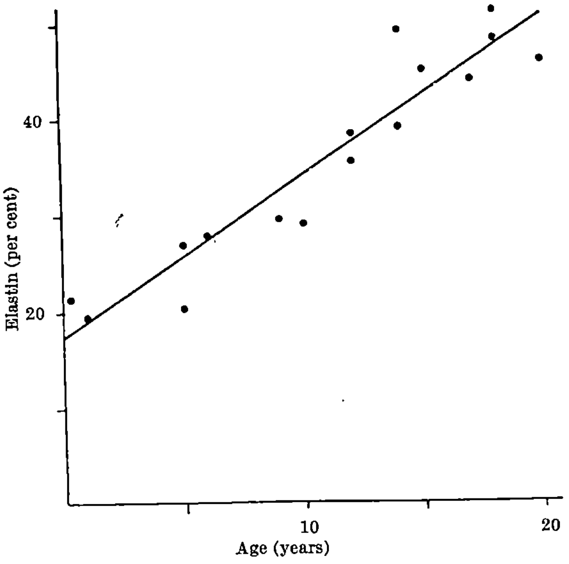

Fig. 1

as already described by me. 30 mgm. of the dry triturated matter were taken for analysis.

In Fig. 1 the results of analyses are expressed as percentage of elastin in the dry weight of the sample and plotted against age at time of death. Statistical analysis of this graph shows a highly significant increase in elastin content of the human aorta with age between 0 and 20 years (correlation coefficient: $r = 0{\cdot}877$; Student's $t = 6{\cdot}81$; $P < 0{\cdot}001$). The equation of the regression line is $y = 17{\cdot}5 + 1{\cdot}65\,x$.

Further investigations in progress in this laboratory seem, on the other hand, to demonstrate a significant decrease of elastin content in the aorta after 20 years until old age.

Lack of Effect of Coenzyme Q_{10} on Coumarin-induced Hypoprothrombinæmia

Several coumarin and indanedione drugs are capable of inducing hypoprothrombinæmia, presumably by interfering with the cofactor role of vitamin K in prothrombin synthesis. This role of vitamin K, probably involving electron transport, can be competitively inhibited by coumarins, and the inhibition competitively overcome by large doses of vitamin K (ref. 1).

Recently[2] another group of quinones, the coenzymes Q, has been shown to be involved in electron transport. Numerous similarities of coenzymes Q to the vitamin K group[3] have led to the following comparison of vitamin K_1 and coenzyme Q_{10} as regards inhibition of the prothrombin response to a coumarin anticoagulant.

Table 1. Effect of Coenzyme Q_{10} on Prothrombin Response to Acenocoumarin in Normal Guinea Pig*

	Prothrombin time (sec.)	
	Range	Average
Q_{10} vehicle (1 or 2 c.c.)	31–34	33
Q_{10} (10 or 20 mgm.)	31–36	34
Acenocoumarin (1 dose) 4·5 mgm. in 1 c.c. H_2O	49–62	55
Acenocoumarin (1 dose) + Q_{10} 10 mgm.	53–130	79
Acenocoumarin (2 doses 24 hr. apart) each 4·5 mgm.	99–> 180	> 149
Acenocoumarin (2 doses 24 hr. apart) + Q_{10} 10 mgm.	78–177	134
Acenocoumarin (2 doses 24 hr. apart) + vitamin K_1 ('Mephyton') 10 mgm.	35–50	43

* All drugs were given intraperitoneally. Each group consists of at least four animals.

Guinea pigs were treated with sodium acenocoumarin, vitamin K_1, coenzyme Q_{10} (10 mgm./c.c.) in solvent vehicle (consisting of 'Emulphor' and dimethylacetamide, and the co-enzyme Q_{10} kindly provided by Dr. Karl Folkers of Merck, Sharp and Dohme, Rahway, New Jersey) and solvent vehicle as indicated in Table 1. Blood specimens were obtained 24 hr. after the last dosage, and the prothrombin time estimated by techniques previously reported[4]. The relatively long normal prothrombin time by the method employed is characteristic of the species. The results in Table 1 demonstrate that coenzyme Q_{10} has no vitamin K-like protective effect against acenocoumarin-induced hypoprothrombinæmia under the experimental conditions used.

Table 2. Effect of Coenzyme Q_{10} on Response to Acenocoumarin in Acutely Starved Guinea Pigs

	Prothrombin time (sec.)	
	Range	Average
Acenocoumarin 4·5 mgm. + 1 c.c. saline	40–55	48
Acenocoumarin 4·5 mgm. + coenzyme Q_{10} 10 mgm.	60–75	68
Acenocoumarin 4·5 mgm. + 1 c.c. vehicle	50–87	63

To test this observation further, the experiment was repeated in 12 animals deprived of food the day prior to and after dosage. The results are presented in Table 2. It is evident that coenzyme Q_{10} had no protective effect.

It is concluded that in the guinea pig, exogenous coenzyme Q_{10} has no vitamin K-like antagonistic action against the hypoprothrombinæmia induced by acenocoumarin.

Pinnal Anaphylaxis: an Additional Anaphylactic Site

In some respects the mouse is a desirable experimental animal for immunological studies. Because of its small size and high reproductivity it can be used in statistically meaningful numbers. Availability of highly inbred strains minimizes variation in individual response and makes it possible to select strains of maximal sensitivity[1].

In other respects the mouse has certain drawbacks. One is its relative refractoriness to anaphylactic challenge. Another is the limited body-area available for local anaphylaxis.

Ovary[2] demonstrated the possibility of producing passive cutaneous anaphylaxis in the skin of the back of the mouse. He found that about 100 times as much rabbit antibody is necessary to induce local sensitization of the mouse skin as compared with the guinea pig. With high concentrations of reagents he was effectively limited to two injection sites, one on each side. His intravenous challenging dose of antigen was 1·2-mgm. hen ovalbumin.

The present investigation was undertaken with the objective of increasing the number of available sites for local anaphylactic challenge in the mouse and, perhaps, introducing more sensitive sites than the skin of the back. The ear was selected for several reasons. It is a translucent structure, in which collection of dye released by local anaphylactic reaction would be readily apparent. Though preferential inducement of capillary permeability in the ear, as compared with the skin of the back, is less marked in the mouse than in the rat and guinea pig, Feldberg and Miles[3] did find a distinctly greater response to 48/80 over the head, shoulders and limbs than elsewhere on the mouse skin. Finally, as a paired structure, one ear can, if desired, serve as a control to the reaction in the other. This initial communication reports primarily on the production of passive anaphylaxis in the ear of the mouse, using a partially purified duck ovalbumin and the rabbit antiserum to it.

The skin over the ear is very fine, and it is impracticable to carry out intradermal injection. Therefore, it was decided to instil the sensitizing serum subcutaneously. The mouse was lightly anæsthetized with ether. Using 26 gauge × ½-in. needles, a tenfold dilution of the antiserum was injected between the skin and cartilage on the outer aspect of one ear, while saline was injected similarly in the other. Volume was controlled by sight, a small bleb being raised. This approximates to 0·025 ml. of fluid per site.

At intervals varying from 30 min. to 24 hr. after sensitization the mice were injected intravenously in a tail vein with 0·25 ml. of a solution containing 1·25 mgm. of 'Pontamine' sky blue and 0·1 mgm. of the duck ovalbumin. Control mice were challenged with dye alone. A positive reaction, as exhibited by the local extravasation of blue dye in the ear, generally appeared within 10 min. and was complete after 30 min. The saline-injected control ears in antigen-challenged mice were uncoloured (apart from an occasional pin-prick of blue at the point of passage of the needle through the skin), as were both ears of the mice challenged with dye alone. Fig. 1 shows the complete results of a single experiment: no selection or elimination has been made. Positive reactions have been obtained when antigen challenge has been carried out as early as 30 min. and as long as 24 hr. after passive sensitization of the ear, 2–3 hr. being the optimal time for production of uniformly strong reactions.

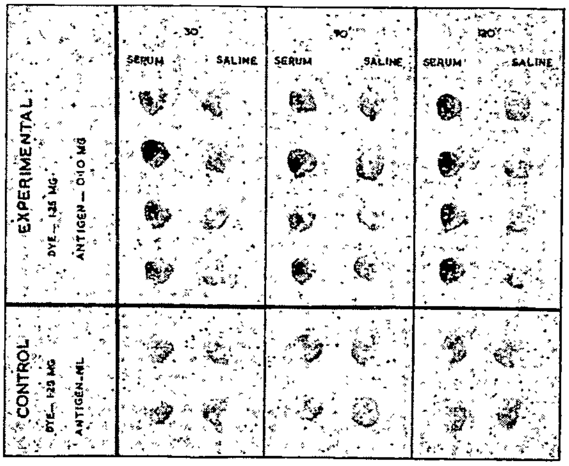

Fig. 1. Passive pinnal anaphylaxis in the mouse. Ears seen from inner aspect

The term pinnal anaphylaxis seems most appropriate to the phenomenon as the entire thickness of the pinna appears to be permeated with the dye: the skin on both the inner and outer aspects of the ear, the subcutaneous spaces and the cartilage.

Passive pinnal anaphylaxis has also been produced in intravenously blued mice on subcutaneous challenge with as little as 0·5 mgm. of duck ovalbumin. It has also been demonstrated in the guinea pig both on intravenous and subcutaneous challenge with duck ovalbumin and grass pollen extracts, using appropriate antisera. Quantitative studies, active pinnal anaphylaxis and other extensions and applications of the phenomenon are under investigation.

I wish to thank Miss Janet Dewdney for technical assistance, and Douglas F. Lawson for photographing the results.

Cytochrome *c* in the Heart of the Turtle

In a thesis on the anaerobic metabolism and mechanical efficiency of the heart of the turtle, by R. Blake Reeves[1], there is evidence that this heart is able to work efficiently for any length of time without access to oxygen (nitrogen anoxia). In view of this remarkable quality we found it interesting to investigate the content of cytochrome *c* in the heart of the turtle (*Testudo graeca*). To our knowledge, no such data are available in the literature[2–4], although reports on the cytochrome *c* content of the heart of the frog have been published by Keilin[5].

Six turtles were killed by ether and the hearts were weighed (3·5 gm.). The cytochrome *c* was extracted according to a method described by one of us (G. B.[4]); instead of 'Amberlite *XE*-64', however, 'Duolite *CS*-101' was used in the present investigation.

On analysis of the final eluate (reduced state) there was a typical cytochrome *c* spectrum with absorption maxima at 417, 521 and 550 mμ. The ratio $\frac{550\text{ m}\mu\text{ red.}}{280\text{ m}\mu\text{ ox.}} = 0{\cdot}3$ was very low compared with those of previous investigations[5]. Using the value of $E^{1\text{ cm.}}_{1\%}$ 550 mμ = 22·7 for crystalline bovine cytochrome *c*[6], the concentration of cytochrome *c* in turtle heart muscle was 2·7 mgm./100 gm. wet weight, which is about the same content as that of heart muscle of the frog[3].

We have found it of some interest to report this observation in connexion with the concept of the electron transport particle advanced by Green[7]. Further investigations on respiratory enzymes in poikilotherms are in progress.

RADIOBIOLOGY

Failure of a Dog to discriminate between Strontium-90 and Calcium given Orally

The ability of a mammal to discriminate against strontium-90 has been the subject of intensive study in recent years. A recent summary of the results of several experiments using a variety of species and experimental approaches indicated that bone discrimination against strontium-90 in favour of calcium can vary from 2 to 4 (ref. 1). This means that the ratio of strontium-90 to calcium in bone as compared with the diet, referred to as the observed ratio, ranges from about 0·25 to 0·50 (ref. 2). These observations have led to the general belief that the mammal always discriminates against strontium-90 deposition to some significant extent.

There are a few reports of a lack of discrimination against orally administered strontium-90. Comar observed a ratio of 1·0 in cattle given a single oral dose of strontium-90 or calcium-45 (ref. 3). No work has been reported in which large animals received strontium-90 orally for long periods of time. However, rats were fed throughout their lifetime on a constant strontium-90/calcium diet and exhibited a ratio of 0·28 (ref. 4).

This investigation is concerned with beagles which were fed a constant diet of strontium-90 (1·8 μc. strontium-90/gm. dietary calcium) from the beginning of fœtal ossification (20–30 days after mating) until the pups reached early adulthood (540 days of age). It had previously been noted that the observed ratio between the fœtus and the dam's diet was 0·28, but that the growing pup, when maintained on the same diet, appeared to exhibit a ratio of about 1·0 (ref. 5). One of these pups was maintained on this same diet, first, through the dam during both the last half of gestation and the period of lactation, and secondly, from weaning until 18 months of age, at which time it was killed. The diet fed the dam and her litter was composed of 60 per cent dry kibbled ration to which were added 20 per cent beef and 20 per cent (by weight) water, including the strontium-90 dose. Dietary calcium was essentially all in the dry ration, which, by the classic permanganate method, was found to contain 3·3 per cent calcium by weight. Strontium-90 was mixed into the complete ration so that there were 1·8 μc. strontium-90 per 1·0 gm. calcium at the date of killing. The diet was fed *ad libitum* throughout the experiment to ensure a physiological approach.

The beagle grew normally and was in excellent condition throughout the experiment. It exhibited no lesions either radiographically or on gross and sub-gross examination of the organ systems. The humerus, a rib, and one half of the mandible including teeth were removed, stripped of their muscular attachments, and stored in acetone. The bones were dried later and the humerus was sawn into the eight pieces which are specified in Table 1. Each sample was ashed and then analysed for strontium-90 and calcium. The β-detector used was a well-type plastic scintillator; details of the strontium-90 measurement have been reported in ref. 6. Calcium in the bone samples was determined complexometrically with ethylenediamine tetraacetate (EDTA), which contained a small amount of magnesium chloride, at $p\text{H} > 10$ using eriochrome black *T* as the indicator. Magnesium in these samples comprised about 1 per cent of the calcium on a molar basis. The results are given in Table 1.

Table 1. CONCENTRATION OF STRONTIUM-90 IN BONE FOLLOWING CONTINUOUS EXPOSURE BEGINNING *in utero* TO 18 MONTHS OF AGE

Samples	gm. calcium	gm. calcium/ gm. ash	μc. strontium-90*	μc. strontium-90*/gm. calcium
Proximal epiphysis	0·260	0·391	0·50	1·9
Proximal epiphyseal plate	0·724	0·398	1·2	1·7
Proximal metaphysis	0·744	0·392	1·3	1·8
Proximal diaphysis	0·541	0·393	1·0	1·8
Mid-diaphysis	0·475	0·388	0·97	2·0
Distal diaphysis and metaphysis	0·476	0·388	0·93	1·9
Distal epiphyseal plate	0·689	0·389	1·3	1·9
Distal epiphysis	0·207	0·392	0·43	2·1
Entire humerus	4·12	0·390	7·7	1·9
Rib	0·492	0·386	0·94	1·9
Left mandible with teeth	3·68	0·381	7·4	2·0
Diet				1·8

* At date of killing.

We conclude then that the integrated effect of an exposure of a beagle to an essentially constant dietary strontium-90/calcium level which began *in utero* and continued to young adulthood is that the relative strontium-90/calcium content of the bone is the same as that of the dietary environment. Furthermore, we can compare the distribution along the length of the humerus and in different bones, and the variation is not significant at the 95 per cent confidence-level. Thus the macroscopic distribution in bone does not vary from bone to bone or from trabecular to cortical bone.

Our observation of a value of unity for the ratio in contrast with other reports of lower values serves to emphasize the complications in measuring the over-all effect of many variables, namely, species, age, nutrition, duration of exposure. Finally, we recognize that 1·8 μc. strontium-90/gm. calcium is quite a high level, and, although the skeleton of the dog appeared normal in all respects, our observations do not preclude the possibility of microscopic alterations in bone growth and remodelling processes which may have affected the results.

We thank Dr. J. Luick and Dr. H. Parker for treating the dog, and D. R. Atherton and F. W. Bruenger. This work was supported by the United States Atomic Energy Commission.

Carbon-14 from Nuclear Explosions as a Short-term Dating System: Use to determine the Origin of Heartwood

THE concentration of carbon-14 dioxide in the atmosphere has been increasing since 1954 in a manner shown (for the southern hemisphere) in Fig. 1 (refs. 1,2). This results from carbon-14, produced in nuclear explosions and carried up into the stratosphere by the associated heat, slowly diffusing into the atmosphere. This phenomenon can be used as a short-term dating system. Its use to study the mechanism of heartwood formation is described here.

It is not known if the heartwood extractives present in the heartwood of a tree are the result of 'waste' products of metabolism of the tree at the time of formation of the heartwood, or whether they represent material which has always been present in the sapwood ring and which is converted into heartwood extractives when the wood is converted from sapwood into heartwood. In general, the first hypothesis is favoured. To examine this point, the three outer heartwood rings (the 12th, 13th and 14th rings counted from the outside) of a *Pinus radiata* (total number of rings, 24) felled on August 4, 1959, in the Kaingaroa Forest, New Zealand, were taken and the heartwood extractives removed by acetone and ethyl acetate extraction in a Soxhlet apparatus.

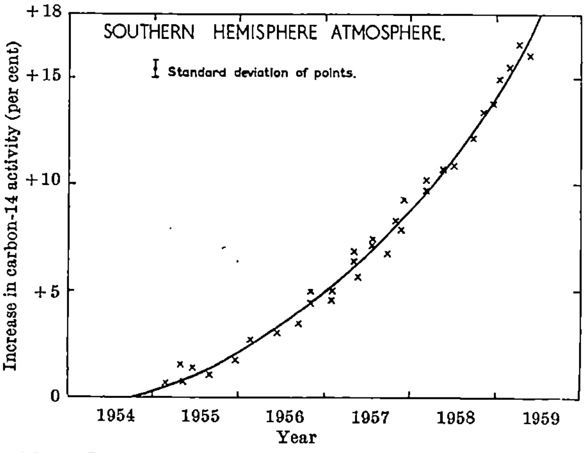

Fig. 1. Increase of carbon-14 in southern hemisphere atmosphere (after Ferguson, ref. 1)

Cellulose was then extracted from the residue. The cellulose and heartwood extractives were then converted to carbon dioxide and counted in the Institute of Nuclear Science low-level carbon-14 counter. The results (all corrected to the same carbon-12/carbon-13 ratio to allow for any isotope effect in the tree or in the experimental manipulation) are given in Table 1.

Table 1. ACTIVITY OF SAMPLE IN COUNTS PER MIN. FOR A 1-ATMO. COUNTER FILLING

All samples corrected to same carbon-12/carbon-13 ratio to correct for isotope effect in the metabolism of the tree and in laboratory manipulation. σ = Standard deviation of the counting

	Cellulose	Heartwood extractives	For comparison, the atmosphere at the time of formation of heartwood is given
Outer ring of heartwood	39·5 $\sigma = 0{\cdot}17$	39·7 $\sigma = 0{\cdot}17$	47·2
First inside ring	39·7 $\sigma = 0{\cdot}17$	39·8 $\sigma = 0{\cdot}17$	44·8
Second inside ring	39·4 $\sigma = 0{\cdot}17$	39·1 $\sigma = 0{\cdot}23$	42·6

It is seen that for a given ring of heartwood, the extractives correspond in activity to the cellulose and not to the atmosphere at the time of their conversion from sapwood to heartwood. The activity of the cellulose corresponds to the activity of the atmosphere when it was the outer ring of the tree (before nuclear explosions).

More specifically, it might be said that (at the 99 per cent statistical confidence-level) less than 6 per cent of the carbon in the heartwood extractives in the outer ring of the heartwood comes from the atmosphere in the year of its conversion from sapwood to heartwood. This might suggest that the sapwood of a pine tree always contains the material which will be converted to the heartwood extractives when that portion of the tree is converted from sapwood to heartwood. This raises the interesting theoretical possibility of artificially inducing the formation of heartwood.

It is hoped to publish later a detailed account of this and related work.

It should be pointed out that this phenomenon of increase of carbon-14 in the atmosphere provides a short-term dating system of great value for biological and other problems[2]. Due to exchange with the oceans, this unique situation will not last for more than a few years[3]. Thus, full use should be made of this effect by as many workers as possible in the immediate future.

The experimental work described in this communication was carried out when I was on the staff of the Institute of Nuclear Science, Lower Hutt, New Zealand. I thank the Forest Research Institute, Rotorua, for supplying the samples.

Removal of Internally Deposited Radionuclides by Triethylenetetraamine-hexaacetic Acid

Increasing the number of donor groups in chelating agents can give rise to the formation of more stable chelates[1–3] and, therefore, to a higher mobilization of internally deposited trivalent and other metal ions of higher valency. This has been demonstrated with ethylenediamine - NNN′N′ - tetraacetic acid (EDTA) and diethylenetriamine-NNN′N′N″-pentaacetic acid (DTPA)[4,5], that is, with chelating agents with 6 and 8 donor groups respectively. For this reason extension of this work to the 10-dentate triethylenetetraamine - NNN′N′N″N‴ - hexaacetic acid (TTHA) seemed to be worth while.

Carrier-free cerium-144, yttrium-91 or strontium-85 was injected intravenously in rats 7–9 weeks old averaging 165 gm. in weight. The chelating agents (by courtesy of J. R. Geigy, S.A., Basle) were given immediately or at different time-intervals after the injection of the nuclide. As shown in Table 1, TTHA reduces the radiocerium content of the skeleton more effectively than DTPA, when given simultaneously or immediately after the administration of the nuclide. In the liver, however, under the same conditions, DTPA is more effective than TTHA. The comparative higher effectiveness of DTPA in mobilizing deposited radiocerium from the liver becomes still more pronounced if the chelating agent is administered after longer time intervals, whereas the superiority of TTHA over DTPA in the removal of radiocerium from the skeleton vanished. Analogous results have been obtained for radioyttrium (Table 2); but neither TTHA nor DTPA had any effect on the mobilization of radiostrontium.

The causes for the observed differences in the behaviour of these two chelating agents are not yet understood. It may be assumed tentatively that TTHA forms to some extent polynuclear colloidal chelates which may be metabolized differently from the smaller molecules of the 1 : 1-DTPA chelates. The greater effectiveness of TTHA as compared with DTPA in the removal from the skeleton—the critical organ for most radionuclides—of radiocerium and radioyttrium can be of therapeutical value in certain cases and justifies further investigations on other radionuclides, especially plutonium.

Incorporation of Phosphorus-32 into Urinary Concretions forming on Zinc Implants in Rat Bladders

It has been proposed that labelling with radioisotopes might be useful in studying the rate of formation of urinary calculi in experimental animals as a function of environmental conditions. The proposal was based on the fact that in siliceous urinary stones of bovine origin, which contain traces of phosphorus and calcium, diffusion and subsequent exchange of phosphorus-32 and calcium-45 with the non-radioactive counterparts of the stone material do not readily occur across the mucoprotein laminations[1]. It was felt that if stone formation occurs layer by layer, short-term massive administration of phosphorus-32 to an experimental animal forming a laminated calculus would result in incorporation of the radionuclide into a single or limited number of laminations, and that subsequent exchange into other laminations would be negligible. Further, if administration of phosphorus-32 were then stopped, and exchange from other parts of the body did not cause significant levels of phosphorus-32 in urine, subsequent laminations would be relatively free of label. Therefore periods of exposure to various environmental conditions could be alternated with periods of administration of isotope, and the amount of material deposited between the laminations containing the isotope would serve as a measure of the effect of environment. The results reported here are from preliminary experiments designed to assess certain aspects of the usefulness of this technique in studying calculi formation.

Rats were chosen as the experimental animal since it has been possible to form artificial calculi on zinc implants in this species readily[2,3]. It was deemed necessary to determine the urinary excretion of phosphorus-32 following massive doses of that isotope in order to establish whether or not the urinary level would subside rapidly enough to ensure that incorporation would become negligible between doses. Results from typical determinations of the excretion of urinary phosphorus-32 after a massive dose (40 μc./rat) are shown in Fig. 1. The results indicated that excretion of that isotope in the urine following administration decreased rapidly and was largely terminated after 8–10 days. The possibility of labelling single or a few laminations seemed feasible.

Thirty rats were therefore implanted with zinc pellets by techniques previously described[3] to induce calculi formation. The rats were fed 15 gm. of ground laboratory rat chow per rat per day. One group received 0·40 gm. of $CaHPO_4.2H_2O$ per rat per day as a supplement and other groups received 0·38 gm. of K_2HPO_4, or 0·086 gm. of tetraethyl silicate. An additional group served as controls.

The stones removed at autopsy (10 days after the second administration of phosphorus-32) were washed, dried and embedded in epoxy resin to serve as a mount. The mount was ground to expose the stones. Further careful grinding removed enough material to allow examination of a central transverse plane of the specimens. Microautoradiographs were prepared as previously described[1].

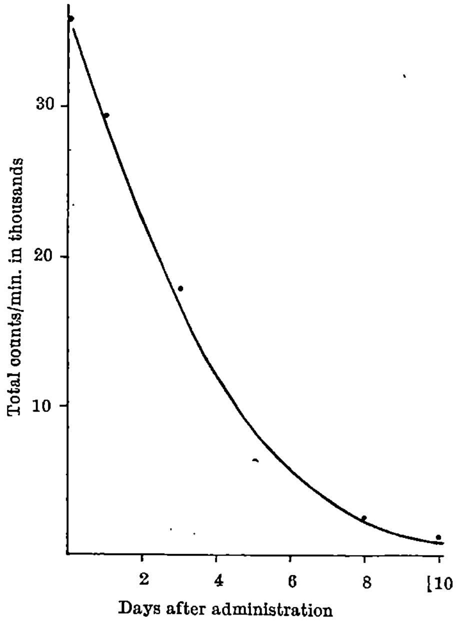

Fig. 1. Excretion of phosphorus-32 in the urine

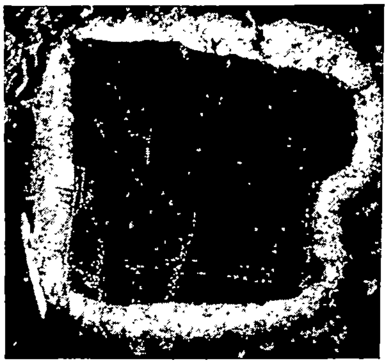

Fig. 2. Typical mounted rat calculus showing the zinc implant in the centre with the concretion surrounding the implant

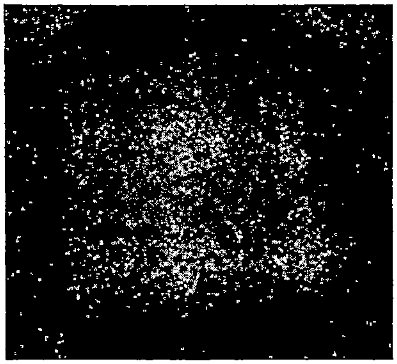

Fig. 3. Microautoradiograph of the stone shown in Fig. 2

Fig. 2 shows an example of the mounted stones from the group receiving calcium phosphate supplement and Fig. 3 shows a microautoradiograph of the same stone. The results were encouraging. There was sufficient phosphorus-32 incorporated to provide adequate exposure for the nuclear-track plate in 4–5 days, in spite of the relatively short half-life of phosphorus-32. The apparent lack of incorporation into two separate concentric rings corresponding to each dosage period was due to the fact that these stones, as shown by diffuse, low-intensity mucicarmine staining, were not grossly laminated with alternate inorganic and mucoprotein layers. The lack of mucoprotein layers apparently allowed random exchange of phosphorus to occur throughout the stone. Stones which were removed from other rats of the other groups and which contained enough deposit to yield a satisfactory microautoradiograph were similar to that shown.

Incorporation of phosphorus-32 was more than adequate for microautoradiography. It was somewhat lower in the rats receiving a tetraethyl silicate supplement than in the others. With silicate supplement, the stones were probably of the high-silicon but low-phosphorus type[3], and hence less incorporation would be expected. None of the stones was grossly laminated, and therefore showed only slight separation into distinct rings labelled with phosphorus-32.

If present experimental work on formation of siliceous calculi on zinc implants in the bovine species provides an adequate means of producing such calculi, then it is anticipated that the phosphorus-32 labelling technique will be very useful. Most siliceous bovine stones are strikingly laminar[1]; this is not the case with stones from rats, and bovine stones do contain enough phosphorus to ensure that sufficient incorporation of phosphorus-32 would be expected with little inter-laminar exchange. These preliminary results suggest that the method offers promise in the study of the rate of formation of bovine calculi under experimental conditions.

HÆMATOLOGY

Haptoglobin Patterns in Cord Blood Serums

Although haptoglobin is almost always present in normal adult serums, it is demonstrable in only about 10 per cent of cord blood serums by the technique of starch-gel electrophoresis[1]. The factors accounting for this large percentage of ahaptoglobinæmic new-borns are obscure. The present communication is based on a survey of cord-blood serums undertaken in an attempt to evaluate some of the factors accounting for the high frequency of ahaptoglobinæmia in the new-born. At the same time, work was carried out to substantiate that the new-born baby with detectable haptoglobin produced it himself.

Two hundred and twelve cord blood serums were subjected to the horizontal starch-gel electrophoresis technique of Smithies[2], using Poulik's discontinuous buffer system[3]. Before electrophoresis, sufficient hæmoglobin was added to each serum to saturate completely any haptoglobin present. One half of each resultant gel pattern was stained with amido black 10*B* to detect protein bands, and the other half with a dilute benzidine stain to locate the haptoglobin–hæmoglobin complexes[4].

Of the 212 cord blood serums examined, 27 (13 per cent) had detectable haptoglobin. As had been noted[5], the patterns, though characteristic, were frequently faint or not detectable with the amido black, and clearly definable only with the more sensitive benzidine stain. Haptoglobin typing of these new-born babies' parents revealed no exceptions to the genetic hypothesis of Smithies and Ford-Walker[6]. No unusual haptoglobin types were encountered.

Comparison of hæmoglobin, hæmatocrit and serum bilirubin-levels between the ahaptoglobinæmic new-borns and those with detectable haptoglobin revealed no evidence to suggest that *in vivo* hæmolysis caused ahaptoglobinæmia (Table 1).

Of fourteen cord blood serums examined from new-born babies with birth-weights less than 2,500 gm., three showed haptoglobin. The smallest tested, with an estimated gestational age of 28 wk. and a weight at birth of 1,106 gm., had haptoglobin of the 2–2 type. The mother had haptoglobin type 2–2 as well.

Table 1. Comparison of New-born Babies with and without Haptoglobin

Determinations*	Ahaptoglobinæmic new-born babies No. tested	Mean	Range	New-born babies with haptoglobin No. tested	Mean	Range
Hæmoglobin, gm. per cent	182	17·3	12·0–23·2	27	16·9	13·6–21·2
Hæmatocrit, per cent	180	58	40–78	26	59	45–80
Serum bilirubin, mgm. per cent	182	6·4	1·0 –18·0	26	5·7	2·0–14·0

* Performed at 2 days of age.

A higher number (13 of 27) of new-born babies with *Hp* 1–1 was found than would be expected in a randomly selected, predominantly Caucasian population such as this series represented. This was probably due to the greater technical ease of detecting the single band *Hp* 1–1 type when the total serum haptoglobin concentration is low.

In 12 of the 27 instances of cord blood serums with detectable haptoglobin, the mother's type differed from that of her offspring. This finding is indicative of the production of haptoglobin *in utero* by these twelve new-born babies. Of these twelve heterospecific baby–mother haptoglobin combinations, nine new-born babies showed *Hp* 1–1. For these nine it might be argued that the smaller molecular weight haptoglobin 1 species crossed the placenta from their *Hp* 1–2 mothers, to give *Hp* 1–1 patterns in the new-born serum. However, in the remaining three heterospecific baby–mother combinations, the new-born was *Hp* 1–2. The mothers of two of these had *Hp* 2–2 patterns, so their offspring must have produced the *Hp* 1 species of molecule *in utero*. The mother of the third new-born had *Hp* 1–1, giving evidence that her *Hp* 1–2 offspring must have produced the *Hp* 2 species of molecules under its own genetic control. This evidence for the fœtal production of haptoglobin corroborates the findings of Galatius-Jensen, who reported four mother new-born haptoglobin combinations with differing types in mother and baby[5].

We thank Dr. Stewart H. Clifford, project director at the Boston Lying-in Hospital, for making the hæmoglobin, hæmatocrit and bilirubin values available to us.

Serum Factor Gm^a among the Iranians

Of all the genetically determined serum constituents which have been called *Gm* factors, the factor Gm^a, discovered by Grubb[1], is the most frequently studied from the point of view of its distribution among different populations. Hitherto, the proportion of $Gm(a+)$ subjects found among persons of the white race has varied between 67 and 39 per cent (Table 1).

We have examined 296 Iranian subjects, coming from different regions, whose blood samples were taken at the Transfusion Centre of the Iranian Army, at the time of their medical examination for military service. These subjects were twenty years old and apparently in good health.

Table 1. The Serum Factor Gm^a among the Various Populations of the White Race

Population	No. tested	*Gm*(*a*+) (per cent)	*Gm*(*a*−) (per cent)	Ref.
Lapland	110	67·3	32·7	1
Finland	477	65	35	4
England	133	61	39	5
Norway	320	60·6	39·4	6
Sweden	360	59·7	40·3	7
Australia	100	58	42	Kirk, 1948
Denmark	1,084	55·6	44·4	8
France	300	57·3	42·7	3
France	1,000	51·7	48·3	9
France	300	54·3	45·7	10
Italy (south)	125	40·2	59·8	5
Greece	308	39	61	9
Poland	167	39·5	60·5	12

The sera were separated from the clots at the Transfusion Centre, put in sterile bottles, sealed and sent by air to the laboratory for study.

The determination of the factor Gm^a was carried out by the tube technique with the same anti-*Rh* serum as that used in our previous work[2,3], and with the same serum from patients suffering from rheumatoid arthritis. These reagents, as well as the erythrocyte samples coming from the same donors, had thus been previously selected and controlled.

Out of the 296 sera examined, we found 163 *Gm*(*a*+) and 133 *Gm*(*a*−), that is, 55·4 per cent *Gm*(*a*+) and 44·6 per cent *Gm*(*a*−) respectively.

As the subjects examined came from different parts of Persia, the distribution was calculated separately for each of the 13 groups which could be defined.

The results for seven of them are presented in Table 2. The number of individuals coming from other regions (Mazadran, Kermanchah, Pharse, Kurdestan, Gorgan, Kerman and Yazd) was too small to allow the calculation of the frequency to have any significance.

Table 2. Distribution of the Gm^a Factor in the Different Provinces of Iran

	No. tested	Number *Gm*(*a* +)	*Gm*(*a* +) (per cent)
Azerbaijan	48	26	54·1
Gilan	45	25	55·5
Tehran	57	31	54·3
Isfahan	38	21	55·2
Kashan (QOM)	27	16	59·2
Hamadan	19	9	47·3
Khurasan	19	12	63·1

Table 3. Relation between the Gm^a Factor and the Blood Groups

	No.	Per cent	*Gm*(*a*+)		*Gma*(−)	
			No.	Per cent	No.	Per cent
A	89	30·1	44	27·0	45	33·8
B	71	24·0	45	27·6	26	19·6
O	115	38·8	63	38·6	52	39·1
AB	21	7·1	11	6·8	10	7·5
Total	296		163	55·4	133	44·6

So far as the relations between the factor Gm^a and the antigens of the blood groups *A*, *B*, *O* are concerned, the distribution gave us a value of χ^2, which was not significant.

A quantitative determination of the γ-globulins was carried out on each of the samples of serum and, as in previous work, no notable differences were observed between the average percentages of γ-globulins of *Gm*(*a*+) and *Gm*(*a*−) subjects.

Thus, the distribution of Gm^a factors among the Iranians is nearly the same as that previously found for persons of the white race.

HISTOCHEMISTRY

Histochemical and Homogenization Studies of Mitochondrial α-Glycerophosphate Dehydrogenase in the Nervous System

An insoluble brain enzyme capable of oxidizing α-glycerophosphate[1] has been shown to be part of a purely mitochondrial system which resembles succinate dehydrogenase in that pyridine nucleotides do not participate in electron transfer[2]. Histochemical localization of this activity in mammalian nervous tissue was made difficult by the fact that tetrazolium salts are ineffective electron-acceptors in preparations which oxidize α-glycerophosphate. Maximal reaction-rates, however, were obtained by using 2-methyl-1,4-naphthoquinone (menadione, K_3) as intermediate acceptor. Histochemically, this effect was first demonstrated by Wattenberg in liver slices[3]. We found that menadione could be substituted by the sodium bisulphite derivative, but the diphosphoric acid ester ('Synkavite'), vitamin K_1, and 1,4-benzoquinone were ineffective.

In the presence of reduced menadione (K_3H_2), tetrazolium salts are reduced to formazan pigment. This reaction, which is non-enzymic[4], renders histochemically visible the reduction of K_3 by its reductase. Formazan formation by K_3H_2 occurred above *p*H 6·1 and at neutral and slightly alkaline *p*H; this reaction could compete successfully with both auto-oxidation of K_3 and the activity of K_3H_2-oxidase (compare ref. 5). At *p*H 7·4 we found the rate of tetrazolium reduction by rat brain mitochondria in the presence of K_3 to be about 50 per cent higher with α-glycerophosphate than with succinate as substrate. This result compares favourably with measurements of respiration-rate in the presence of oxygen[6].

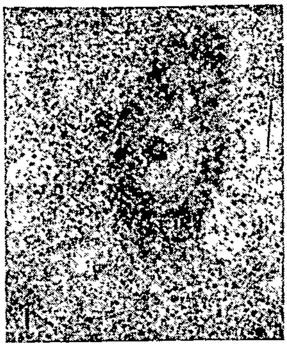

Fig. 1. Rat spinal cord. α-Glycerophosphate–menadione reductase activity in oligodendrocytes. The inactive motor ganglionic cell is counter-stained with thionine. (× 560)

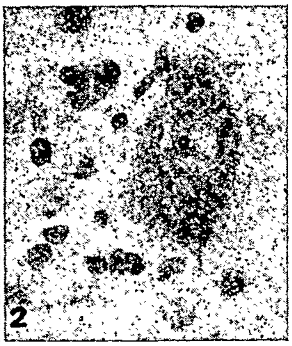

Fig. 2. As Fig. 1, but activity inhibited by addition of phenyl-indane-dione. (× 560)

Histochemical reactions were carried out on 2–8μ fresh frozen sections of rat tissue which were incubated for 15 min. at 22° in media containing substrate (10^{-2} M), 3-(4·5-dimethylthiazolyl-2)-2·5-diphenyl tetrazolium bromide (MTT) (10^{-3} M), cobalt chloride (10^{-3} M), *tris*(hydroxymethyl)aminomethane buffer *p*H 7·4 (0·1 M), sucrose (0·25 M), polyvinylpyrrolidone (1 per cent). High activity with α-glycerophosphate as substrate was observed in neuroglia (Fig. 1) in cells of choroid plexus, in ependyma and in vascular structures. Moderately strong activity was observed in ganglionic cells in certain areas (for example, spinal ganglia); motor neurones were inactive.

Quantitative studies were carried out on rat brain homogenate using the histochemical systems and the results are shown in Table 1. The specific activity of washed brain mitochondria (prepared according to ref. 7) was compared with the activity of the remainder of the cytoplasmic fraction containing soluble flavoproteins.

* Activity expressed as μgm. formazan/mgm. protein/min.
† *a*: Freshly prepared; *b*, frozen-thawed twice.

All the enzyme reactions tested were sensitive to both dicoumarol (10^{-4} M) and *p*-chloromercuribenzoate (10^{-5} M), thus resembling the reactions of a purified brain diaphorase[8]. Selective reduction of the K_3-dependent increase in mitochondrial activity was produced by 2-phenyl-indane-1 : 3-dione (PID) (5 × 10^{-4} M), both *in vitro* and histochemically (Fig. 2). It is likely that PID exerts a similar action on various mitochondrial systems in other organs, since an antagonistic effect of K_3 and PID on uptake of iodine-131 by rat thyroid slices has been observed by Williams and Doniach (unpublished results). Wosilait[9] has demonstrated different inhibitory activity of dicoumarol and PID on vitamin K_1-reductase from dog and rat liver.

Amobarbital can act as inhibitor of both reduced diphosphopyridine nucleotide (DPNH)–coenzyme *Q* reductase[10,11] and purified brain diaphorase[8]. In our experiments its sole effect (at 5 × 10^{-4} M concentration) was to abolish the K_3-induced increase in mitochondrial tetrazolium reduction with succinate and α-glycerophosphate as substrates. On the other hand, mitochondrial activity with pyridine nucleotide-linked systems was not affected. Antimycin *A* partially inhibited direct tetrazolium reduction with α-glycerophosphate and succinate as substrates, but did not impair formazan production via K_3 as the intermediate electron carrier. With DPNH and reduced triphosphopyridine nucleotide (TPNH) as substrates, no effect of antimycin *A* on the rate of formazan formation could be demonstrated in the presence or absence of K_3.

The extensive glial activity of mitochondrial α-glycerophosphate dehydrogenase is of interest in view of the important part played by mitochondrial glycolysis in brain metabolism[12]. The histochemical reaction involving K_3 and α-glycerophosphate probably uses a pathway different from that leading to direct enzymic tetrazolium reduction. In accordance with Wosilait and Nason[13], the present enzyme should be termed α-glycerophosphate-menadione reductase.

HISTOLOGY

Ethylene Glycol Monomethyl Ether, a New Fixative for Histological Work

WHILE studying the guinea pig mast cell[1], we have discovered a new chemical family of histological fixatives, namely, the glycol ethers. These alcohol derivatives, possessing both an ether and an alcohol group, are miscible with most liquids and are excellent solvents for a variety of substances completely insoluble in water. Marketed under the trade names of 'Cellosolves' and 'Carbitals', they have found wide use as solvents for cellulose esters in the lacquer industry. Conversely, they do coagulate and precipitate proteins as well as mucopolysaccharides.

Our initial observations were made on the guinea pig mesentery, with special reference to the labile water-soluble mast cell. Excised specimens were immediately placed in the test solutions (100 per cent concentration, ice cold) and remained there for 18 hr. Afterwards, staining of this naturally thin membrane was achieved with methylene blue (0·25 per cent aqueous, 3 min.), dehydration in absolute ethyl alcohol (2 min., twice), clearing in xylene (5 min., twice), and whole mounts made in a synthetic resin medium (*HSR*).

Ethylene glycol monomethyl ether acetate proved to be the best coagulant fixative of seventeen members of the glycol ether family which were studied. It not only regularly gave solid blue-black mast cells, but also produced a highly desirable intensification of the general staining. The other mesenteric cells showed fine nuclear detail, and collagen fibres were distinct. Significantly, the parent substance, 'Cellosolve' (ethylene glycol mono-ethyl ether), was also an excellent fixative of the mast cell and its use led to almost selective staining of the mast cell. The mesentery and its other cells stood as a pale almost non-staining background for the vivid blue-black mast cells. Here the distinct basophilic granules were in evidence and at times the nuclear space was apparent as a non-staining vacuole. The polymorphism of the mast cell was particularly striking. In the control specimens degranulation was not seen. When such mast cell discharge was induced pharmacodynamically, the fixative faithfully captured the free granules.

The excellence of these fixatives for the guinea pig mesentery led us to explore the general usefulness of the glycol ethers in fixation of other mammalian tissue, using standard paraffin embedding and staining procedures. Using normal as well as diseased human skin, as a test object, it was found that ethylene glycol monomethyl ether produced superior fixation of the cellular components even at room temperature. Nuclear detail, colour brightness and contrast, and glycogen fixation were particularly attractive attributes of the slides prepared from 100 different biopsies. However, in some specimens polarization or streaming of the cytoplasm was seen. A variety of stains were used with consistently fine results and it was found that washing out of the fixative was not necessary.

Despite the rather awesome list of available fixatives[2], Baker has pointed out that the number of substances really useful in chemical fixation is still very small[3]. Accordingly, ethylene glycol monomethyl ether and certain of its congeners are recommended as new non-aqueous fixatives deserving of further trial in histological and histochemical work. They may prove particularly rewarding in fixed tissue enzyme assays of water-soluble components. In our laboratory they have been of continuing value in the fixation and staining of mast cells.

This work was conducted under the sponsorship of the Commission on Cutaneous Diseases of the Armed Forces Epidemiological Board and was supported by the office of the Surgeon General, Department of the Army.

BIOLOGY

Adaptive Value of Regenerative Ability

THE view that the distribution of regenerative ability among and within animals is not correlated with the incidence of loss or damage to their organs, and so with survival value, rests very heavily on the work of Morgan[1] on the hermit crab, *Eupagurus longicarpus*. He concluded that the regenerative ability of its various appendages was not correlated with their liability to loss: in particular, the last two pereiopods (thoracic walking legs) and the abdominal appendages, all of which are protected inside the host shell and are rarely lost, regenerate well. He also found that limbs regenerate not only at their autotomy plane, classically regarded as an adaptation to facilitate both escape and regeneration, but also when amputated proximally or distally to the plane. Recent work[2,3] has tended to confirm in some detail the neo-Darwinian view that regenerative ability is correlated with its utility, as measured by the incidence of natural losses. However, since considerable emphasis has again[4] been placed on Morgan's conclusions, it seems worth re-examining his results in the light of a survey made a few years ago (August 1955) on *E. bernhardus*.

Eighty-two individuals, 42♂ and 40♀, were collected at Seaton, south-east Cornwall. They were removed from the shell after fixation in alcohol, and examined under a low-power binocular microscope for fresh and long-standing (natural) losses of eyes, first and second antennæ, pereiopods and abdominal appendages. Long-standing losses include those in the course of regeneration. Recent losses are due mainly to irritation by the fixative. Of the abdominal appendages, the pair of uropods and the left-side members of segments, 3, 4 and 5 are normally present in both sexes. In addition, the left appendage of segment two is normally present in the female, all others being absent in both sexes.

The flagellum of the second antenna fractures readily at any point and the distal end was found missing in most individuals. In addition, eleven showed a recent loss. Losses to the other appendages were:

Table 1

Appendages	♂		♀	
	Fresh	Long-standing	Fresh	Long-standing
Eyes	0	2	0	3
Antennules	0	1	0	1
Pereiopods				
1 (chelæ)	7	5	7	2
2	0	0	3	0
3	0	1 (tip)	2	0
4	0	0	0	0
5	0	0	0	0
Abdominal				
2	normally	absent	0	0
3	3	0	0	0
4	1	2	0	0
5	0	1	0	0
6 (uropods)	0	0	0	0

The incidence of loss is seen to be related to the degree of exposure of the appendages, but with one outstanding exception, the abdominal appendages of the male. Morgan also found some of these appendages missing, but dismissed the matter lightly . . .

"it is possible that the (abdominal) appendages may be occasionally lost". His percentage of losses (4 in 100 crabs) was somewhat less than half that among the pereiopods (29 in 288 crabs), both percentages being similar to those of the present analysis. It was therefore unwarranted to conclude that the ability of the abdominal appendages to regenerate has no useful biological significance.

Morgan claimed that these appendages regenerate virtually as well as the anterior pereiopods, but in fact he had only 10/47 (21 per cent) successful regenerations compared with 10/12 (92 per cent) for the latter. Similar quantitative differences are evident between his records for regeneration at the autotomy plane and those for regeneration elsewhere in a limb. These last results are in essential agreement with more recent results for the thoracic limb of *Asellus*[5], in which the distribution of regenerative ability seems adaptive in every detail. Morgan tended to minimize quantitative differences in ability and to magnify differences in susceptibility to loss.

If he had measured all as carefully as his data permitted, he could have brought out more clearly the unique properties of the uropods and the last two pairs of pereiopods. These properties are confirmed by the present results and by themselves present a far more serious challenge to the 'adaptation' theory. These appendages all regenerate very well, yet are rarely found missing or regenerating. The right-hand pereiopods 4 and 5 appear to be usually shorter and paler than those on the left and the short right uropod is sometimes paler and possibly thinner-shelled than its partner, but these may be normal ontogenetic aspects of the general asymmetry of the posterior part of the body and there was no completely convincing case, in the present results, of natural losses in the process of regeneration.

In explanation of the behaviour of these limbs, it is important to appreciate their indispensable role in movements in and out of the gastropod shell and in anchoring the hermit inside it. The loss of one limb renders its partner also useless, and probably all three pairs are individually indispensable. This would be an adequate adaptive basis for both their high regenerative ability and their lack of autotomy mechanisms. Incidence of loss is related directly to exposure, but also inversely to the indispensability of the appendage. This may explain also why the female, unlike the male, does not lose her other abdominal appendages, which are used to carry the 'berry' after oviposition. A parallel case is the fifth thoracic limb of the mature male *Asellus*[6], both members of the pair being essential to hold the female during the (considerable) period before coition. The limbs autotomize readily in females and immature males. Like the *Eupagurus* limbs in question, the limb of the mature male regenerates well if experimentally amputated.

Simultaneous Eradication of Three Ectoparasitic Species from a Colony of Laboratory Mice

THE mange mites and blood-sucking louse commonly infesting laboratory mice (to the almost certain detriment of survival and fecundity) can be entirely eradicated by modern topical and systemic pesticides. The present communication gives details of a proved, if time-consuming, procedure whereby a one-room colony of four hundred cages was cleared of three of the following ectoparasites (Fig. 1):

Mange mites. (i) *Myocoptes musculinus*[1], off-white; massive brown claspers on third and fourth pairs of legs; concentrates on the body, especially neck and rump; may thickly encrust the skin; clusters of pink eggs on each hair often discolour the coats of albinos. Eradicated.

(ii) *Myobia musculi*[1], all-white; claspers on first pair of legs; concentrates on the head, especially at the base of whiskers and eye-lashes; sometimes causes weeping sores; white eggs, one at the base of any hair. Eradicated.

(iii) *Psorergates simplex*[2], white; no claspers; all stages found together within pustules under the skin, especially facial skin; severe manifestation[3] rare. Virtually eradicated.

Blood-sucking louse. (iv) *Polyplax serrata*, 1 mm. long; highly mobile; silver eggs attached half-way along the hairs. Eradicated.

Prospects of disinfestation. Residual infestations remained after sulphur dust[4], lindane[5,6], tetmosol[6] and dibutylphthalate[3] had been used as whole-body treatments, and none seemed capable of disinfesting an entire colony. Only tetmosol caused no distress to the mice; it was also observed to kill *Polyplax* instantly.

However, at least four pesticides untried by me have some prospect of eradicating all the above mouse pests. The simplest to use would be the systemic

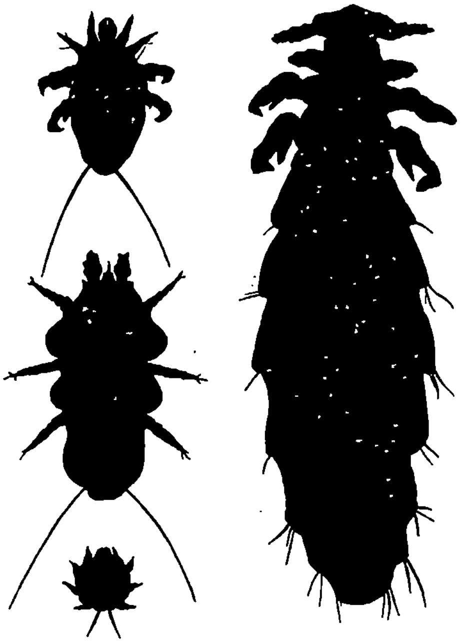

Fig. 1. Representations to scale of the four ectoparasitic species on laboratory mice. The largest is the louse *Polyplax*; the others, from top to bottom, are the mites *Myocoptes* ♀ (the abdomen of the male scarcely protrudes beyond the last legs), *Myobia* and *Psorergates*

pesticides tedion[7,8] and trolene[9], both widely applied to farm animals, if suitable doses for their addition to the food or water can be found for mice. Otherwise, the topical pesticides chlordane or malathion[10] could be tried. A single application of chlordane to fresh bedding is known to eradicate *Polyplax* from mice[4], and the murine mites might be equally susceptible, since those on hamsters were considerably reduced in numbers by the remote action of chlordane painted on to the trays of their cages[11]. Similarly for malathion: a single dip killed all *Myocoptes*[12]; routine treatment of bedding cured a colony of myocoptic and myobial manges where mice were frequently introduced from outside sources[5]; and it might prove effective against *Polyplax*, having been used successfully against lice on birds[13].

The present method uses an aqueous dip of tetmosol and DMC. DMC had already been used in 50 per cent alcoholic solution, first to free a small colony from *Myocoptes*[14], and afterwards a much larger colony from *Myocoptes*, *Myobia* and *Polyplax* (Carter, T. C., and Lyon, M. F., personal communication). In these cases, each mouse was bathed three times at five-day intervals, and very great care was needed to ensure survival. For this reason, after the first room of the larger colony had been disinfested, mice from the remaining rooms were treated at birth by removing the mites with forceps, swabbing the mice once only with the DMC solution, and then fostering them immediately on to already disinfested mothers (Carter, T. C., and Lyon, M. F., personal communication). But disinfestation can be more casual if DMC and tetmosol are presented together in aqueous emulsion, using the tetmosol both to augment the miticidal action of DMC and to be the effective insecticide in the absence of alcohol.

A dip was made by mixing: 2 gm. DMC dissolved in 3 gm. ethanol; 67 gm. tetmosol, and 1 litre warm tap-water. The gift of the DMC, or di-(*p*-chlorophenyl)methylcarbinol, by Sherwin Williams Inc., Cleveland, Ohio, is gratefully acknowledged; the tetmosol, a 25 per cent solution of tetraethylthiuram monosulphide, was supplied by I.C.I. (Pharmaceuticals) Ltd., Wilmslow, Cheshire. The dip was maintained at 30°–37° C. in a water-bath no hotter than 40° C., otherwise mice falling into it could be killed. Mice were given two dippings 1 hr. apart and two further dippings 1–3 weeks later. The first and third dippings were prevented by air pockets from killing every parasite but made the skin thoroughly receptive to the dip on the next occasions; the third and fourth dippings mopped up rare survivors. On each occasion the mice swam for half a minute and were submerged about six times, were drained for three-quarters of a minute while the next mouse was swimming, and then returned to their cages—to their old cages after the first and third dippings, and to clean cages after the second and fourth. A few severely chilled mice had to be specially revived in warm air.

Disinfestation was started when no new litters were immediately expected and the mice could be treated as adults or well-grown weanlings. All mice had the first two dippings within 5 weeks, and many stocks were by then completely disinfested. About a quarter of the mice were required for breeding before their final dippings could be given, and complete disinfestation of these stocks was deferred up to six months and applied to later generations. During this time the disinfested stocks were isolated so far as possible on the upper shelves, and hands were scrubbed before handling them. But no lice and very few mites survived the ancestral second dipping, and recontamination was not observed. The full treatment averages 3 min. per mouse, but much time might be saved by dipping only once in a more concentrated and penetrating emulsion to which a harmless wetting agent such as 1 per cent sodium alkylaryl sulphonate[2] had been added, and by treating several mice together in baskets constructed for the purpose.

Altogether, 1,700 mice were treated without loss. About one thousand of these became parents and were minutely inspected under a stereoscopic microscope at autopsy. In subsequent generations a similar number, representing 10 per cent of sires, have been inspected on the face and back. No *Myocoptes*, *Myobia* or *Polyplax* have been seen in the 2½–3 yr. since treatments were completed, nor have *Psorergates* pustules been recognized in the past half year.

A Natural Hybrid of *Tilapia nigra* and *Tilapia leucosticta* from Lake Naivasha, Kenya Colony

CICHLID fish of the genus *Tilapia* are of considerable importance in both natural fisheries and pond culture in many tropical and subtropical climates, particularly throughout Africa. Certain species have proved to be adaptable to varied environmental conditions, and consequently there has been a considerable artificial dispersion of species beyond their natural geographical range, as far afield as Malaya and Pacific islands, and including high-altitude waters in several parts of Africa. This transportation has brought into contact species which were hitherto geographically isolated, and due, at least in part, to this, there is an increasing number of records of hybridization. Lowe[1] first directed attention to possible hybridization between *T. nilotica* (Linné) and *T. nigra* (Günther), and between *T. nilotica* and *T. esculenta* Graham in Uganda. Yashouv and Chervinsky[2] have crossed *T. nilotica* and *T. galilea* (Artédi) in Israel, and Bard[3] reports a hybrid between *T. nilotica* and *T. machrochir* Boulenger in culture ponds in the Cameroons. More recently, Hickling[4,5] crossed a Malayan strain of *T. mossambica* Peters with another of the *T. mossambica* group from Zanzibar, and Mortimer[6] has hybridized *T. mossambica* and *T. andersoni* (Castelnau) in culture ponds in Northern Rhodesia.

Excluding Lowe's[1] unconfirmed observations, none of these hybrids has occurred in 'natural' waters. The crosses recorded by Hickling[5] and Mortimer[6] were

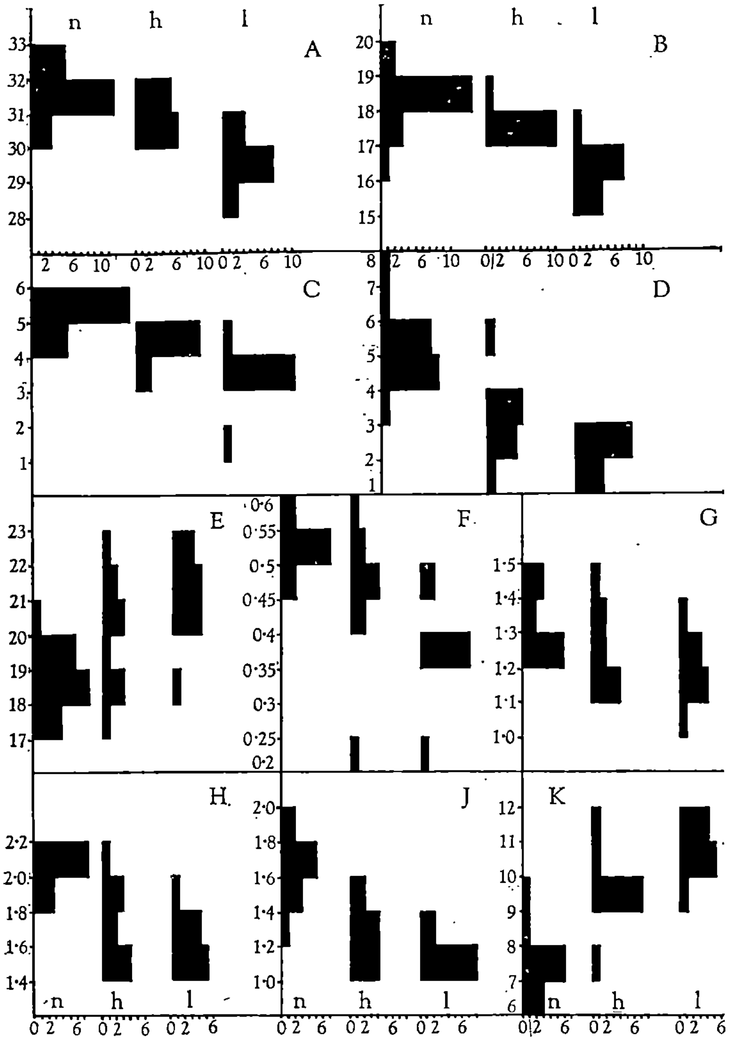

Fig. 1. *Abscissæ:* all figures from left to right, (*n*) *T. nigra*, (*h*) hybrids, (*l*) *T. leucosticta*, as numbers of fish.

Ordinates: (*A*) Lateral line scales. (*B*) Dorsal fin spine number. (*C*) Anal fin spine number. (*D*) Extent of pectoral fins: (1 < vent, 2 < papilla, 3 < anal spine I, 4 < spine II, 5 < spine III, 6 < spine IV, 7 < spine V, 8 < spine VI). (*E*) Gill raker count. (*F*) Ratio of length/width of tooth pad on lower pharyngeal bone. (*G*) Ratio of length/depth of premaxillary. (*H*) Ratio of length/depth of dentary. (*J*) Ratio of length/width of dentary. (*K*) Ratio or standard length/length of dentary bone

the results of deliberate attempts to produce improved strains for fish culture work.

In all the instances mentioned, the species belong to the 'maternal brooder' group of *Tilapia*, in which the female normally broods the eggs and young in her mouth.

In East Africa, *T. zillii* (Gervais), a macrophyte feeder, has been more widely dispersed than most other species, in the hope that it will clear weed-choked waters; and Whitehead[7] has described a cross between the female mouth-brooding species *T. nigra* and the 'substratum-spawning' *T. zillii* in Lake Naivasha and also in a flooded rice paddy field at the Tebere Rice Irrigation Scheme, Kenya. Lake Naivasha is a shallow basin of some eighty square miles, which originally contained only one species, *Aplocheilichthys antinorii* (Boulenger), endemic to Lake Naivasha and southern Ethiopia. During the past forty years, various other species have been introduced: *T. nigra* was stocked to provide forage for the introduced black bass (*Micropterus salmoides* (Le Seur)). Rainbow trout (*Salmo gairdnerii* (Richardson) have also gained access from the affluent rivers and *Lebistes* and *Gambusia* were introduced for mosquito control. Most recently, *T. zillii* was stocked from ponds in Kisumu, Kenya.

In postulating hybridization beween *T. nigra* and *T. zillii*, Whitehead (unpublished work) noted certain similarities between a proportion of his hybrids and *T. leucosticta* Trewavas, although the agreement was not complete. On the basis of Whitehead's[7] communication and some of his unpublished results, Trewavas and Greenwood[8] suggested that the hybrids were in fact *T. leucosticta*, another mouth-brooding species, which had gained access to Lake Naivasha by accidental inclusion in the *T. zillii* stocking. In addition, they did not exclude the possibility of some hybridization having occurred between *T. nigra* and *T. leucosticta*.

The occurrence of both pure *T. leucosticta* and hybrids between *T. leucosticta* and *T. nigra* has been confirmed by more recent work, on Lake Naivasha.

During a routine analysis of some five thousand fish, numerous specimens were collected, the taxonomic characters of which agree in detail with the description of *T. leucosticta* given by Lowe[9]. In addition, however, eleven specimens, of 28–31 cm. total length, were recognizably distinct from both *T. leucosticta* and *T. nigra*, and showed a variable complex of intermediate characters. The field characteristics on which they were originally distinguished were depth of body, profile of head, shape and size of mouth, count of anal fin spines and coloration. Further examination of the meristic and morphometric characters of these specimens confirmed their intermediacy, and a summary of the principal characters is given in Fig. 1.

Confirmation of the hybrid identity has not yet been attempted by artificially crossing *T. nigra* and *T. leucosticta*, but there can be little doubt that hybridization has occurred, and that Whitehead's[7] original description was based on a mixture of pure *T. leucosticta* and *T. nigra* × *T. leucosticta* hybrids. The fact that all these hybrids were mature males and the low proportion in the total population may invite speculation regarding their viability. This cannot be established until a very much wider size-range has been examined, since sexual dimorphism occurs in the growth of both *T. nigra* and *T. leucosticta*, the males being somewhat larger.

This investigation was undertaken as a necessary preliminary to a study of the fishery potential of Lake Naivasha. It is now possible to identify *T. nigra*, *T. leucosticta*, *T. zillii* and *T. leucosticta* × *T. nigra* hybrids in a population formerly considered to be pure *T. nigra* and *T. zillii*. However, the exact taxonomic identity of a large proportion of the Naivasha *Tilapia* still remains to be determined, owing to the very wide and variable range of colour, meristic and morphometric characters which has been encountered.

Further Observations on a Filamentous Saprophyte from Wookey Hole Caves

Work now completed on this unusual organism, found growing in darkness in rather stagnant water of Wookey Hole Caves, Somerset, has yielded some information additional to that reported earlier[1]; but the identity of the saprophyte remains unknown.

The organism, although slow-growing, may be successfully cultured in the light or in darkness on a range of solid and of liquid media, and can readily utilize glucose, sucrose and mannose. A notable feature is its great plasticity of form, which may vary, dependent on the cultural conditions, from septate, branching filaments to chains of rounded cells which almost separate from one another. X-ray diagrams of the cell wall show some similarity to those of yeasts. Usually there are several very small, obscure nuclei per cell, and photosynthetic pigments are lacking. On certain media the organism produces large amounts of oil, especially in old cells; thick-walled chlamydospore-like bodies, which give rise to fine filaments on germination, are formed in some cultures. On media low in glucose, anastomoses are frequent; however, no sexual organs have been observed, despite the wide range of cultural conditions and treatments investigated.

A full, illustrated account of this saprophyte, which seems to show more affinity to the fungi than to the algae, will be given elsewhere[2].

Axenic Seedlings of *Drosera*

Carnivory in higher plants fascinated Darwin[1] and later students of evolution, yet a century-long debate[2] on the extent of *Drosera's* dependence on, and specialization for, insect prey remains inconclusive. A technique for obtaining axenic *D. intermedia* (a sundew) is reported here—a step forward in analysing its biochemical capabilities.

Büsgen[3] preferred seedlings to winter buds as more uniform experimental subjects. Vegetative plantlets are better, as they circumvent genetic variation. However, for purposes of aseptic cultivation, seeds—easier to handle and protected by their hard coat—are best, assuming that vegetative propagation follows. Seeds were collected in September (between ripening and shedding) at Bethel, New York, and stored dry at room temperature for 8 months. For sterilization, seeds were immersed in an aqueous solution of 'Clorox' (5 per cent) plus 'Aerosol' *OT* (0·02 per cent) for 10 min. with constant shaking, then washed three times in sterile distilled water and inoculated in batches of 10–12 from the water to agar slants (composition in Table 1).

Table 1. Composition of Slant Media

Compound	mgm./100 ml. final medium
NH_4NO_3	12·0
KH_2PO_4	6·8
$MgSO_4.7H_2O$	12·0
$Fe(NH_4)_2(SO_4)_2.6H_2O$	0·56
$CaCO_3$ (dissolved in HCl)	2·0
Sucrose	2,000·0
Trypticase (Baltimore Biological Lab.)	50·0
'Complete Supplement No. 10'*	0·5 ml./100
Agar	1,000·0
*p*H 6·0	

* An aqueous solution of *B* vitamins, amino-acids, hydrolysed nucleic acids, and an acid hydrolysate of casein (Hycase, Sheffield) quite similar to 'complete supplement No. 9' given in ref. 4.

For uniformity, seeds for each experiment were sterilized together. Viability of unsterilized seeds was not determined. Of 3,200 seeds on slants stored 3 months at room temperature in the dark, only two germinated. Exposure to indole-3-acetic acid, gibberellic acid, dilute sulphuric acid, high temperature (37° C.), or freezing followed by either high or room temperature, did not enhance germination.

However, several slants left on a west-facing window-sill in September showed 6 per cent germination after one month, suggesting physical germination stimuli. *D. intermedia* in southern New York State normally germinates in March and April on the moist surface of acid bogs. Temperature- and light-alternation, reported stimulatory to germination in various other plants[5], were tried. Freshly inoculated slants were subjected to a cycle of 12 hr. at 15° C. and 12 hr. at 38° C., and either illuminated by two 40-W. 'cool-white' fluorescent lamps or kept in the dark when desired, by wrapping the tubes. Germination was observed after 5 weeks of treatment. As shown in Table 2, seeds subjected to a temperature-cycle plus light showed significant germination, but not when exposed to constant temperature or placed in the dark, at any temperature. No dark period is necessary.

Table 2. Effect of Light and Temperature Alternation on Germination of *D. intermedia*

	Percentage germination*		
	Constant		Alternate Light and dark
	Light	Dark	
15° C. constant	0	0	0
38° C. constant	2	0	0
15°–38° C. alternation	44	2	31†

* Each sample contained about 100 seeds.
† In the temperature–light alternation, the illuminated phase was at 38° C., the dark at 15° C. The reciprocal experiment (light at 15° C., dark at 38° C.), was not done.

Growth is erratic, some seedlings dying quickly, others putting forth several small but well-developed leaves. Media and conditions for sustained growth are not yet satisfactory. As seedlings (Fig. 1) are now readily available, this step is accessible to experiment.

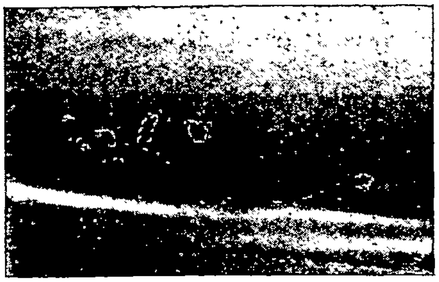

Fig. 1. An axenic *Drosera intermedia* seedling at 1 month (× 4). Black ovals are ungerminated seeds.

Some of this work was done at Brandeis University, Waltham, Massachusetts.

Spore Liberation and Dispersal of Coffee Rust *Hemileia vastatrix* B. et Br.

Nutman, Roberts and Bock[1] have produced evidence recently that *Hemileia vastatrix* uredospores are not liberated into the air from fructifications by wind alone at speeds up to 12·5 miles/hr. and only in small quantities if the supporting leaf flutters violently. They infer that contact of water with the pustules is the principal method of liberation.

However, investigations in the field made during rainstorms at the Coffee Research Station, Ruiru, Kenya, by me in 1956 had shown that wetting of the lower leaf surfaces was usually not very marked and was principally by upward splash from lower leaves. Rust lesions are confined to the lower surfaces and would be too infrequently hit for this to be the predominant method of spore liberation. Microscopic observations of lesions brought in from the field showed that spores were not dislodged by air currents alone to any marked degree. However, with plants grown in the still air of a greenhouse, a light tap on a rusted leaf produced a visible spore cloud. Recently, rust lesions resulting from the inoculation of a coffee plant kindly supplied by the Royal Botanic Gardens, Kew, and kept in a laboratory were found not to liberate spores under calm conditions, but abundant liberation occurred when they were tapped lightly. A lesion tapped at 2–3 week intervals liberated 366,100 spores during three months, and only some further 50,000 could be washed off at the end of this period.

Water droplets allowed to fall on leaves at points situated above fructifications, previously kept in calm conditions, produced abundant spore liberation; for example, ten 5-mm. diameter droplets dropped from a height of 4 ft. liberated 396,600 spores. Further, from such fructifications, currents of air at speeds estimated as less than 1 mile/hr. produced marked liberation. A current not greater than 2 miles/hr. deposited 23,440 spores on 2·5 cm.^{2} of sticky surface held 1 cm. behind a fructification. These observations contrast strongly with those of Nutman[1].

Thus, under field conditions, liberation of spores into the air is probably considerable, though in accord with their rate of fall[1], and as liberation is probably most marked during rainfall, the majority may well be deposited near their point of origin as indicated by Burdekin's[2] observations. The epidemic spread may thus approximate to that expected for a fungus disseminated by rain-splash.

In fructifications kept under calm conditions, stocks of spores are built up by the fascicles of hyphæ which erupt through each stoma forming short, irregular filaments several spores wide. Small mechanical impulses cause these to break off and fall away. Under field conditions, few spores will be ready for liberation at any one time and this may explain Nutman's[1] observations, since his experimental material was brought in from the field.

Production of Symptoms of Barley Leaf-Spot Disease by Culture Filtrate of *Helminthosporium sativum*

It has been reported by several investigators[1–4] that symptoms of some diseases could be reproduced by the action of the culture filtrate on the host plant, instead of using the infecting spores.

During 1957–58 a series of experiments were carried out at the Phytopathological Laboratory, Willie Commelin Scholten, Baarn, Holland, on the susceptibility of the different Dutch barley varieties, namely, Agio, Balder, Piroline and Wisa, to the leaf-spot disease caused by *Helminthosporium sativum* P. K. and B. Pathogenicity tests were carried out under glasshouse conditions where seedlings of the four barley varieties were sprayed with a standardized suspension of *Helminthosporium* spores. The typical brownish necrotic spots appeared on all seedlings. The most resistant variety, as indicated by the size of the necrotic spots, was Balder, followed by Agio, then Wisa, while Piroline was the most susceptible. The same experiments were repeated, but under field conditions, where identical results on mature barley plants were obtained.

It was thought interesting to study the response of these different barley varieties to the probable toxic action of *Helminthosporium* filtrate. Accordingly, the fungus was grown on modified Fries No. 3 medium[4] for 4 weeks at 25° C. The filtrate was passed through a glass filter to get rid of spores and tiny mycelial fragments. The filtrate was distributed into sample tubes. For each of the four barley varieties, four tubes were prepared in each of which three cut shoots were dipped. The cut shoots dipped in the filtrate were left afterwards for 48 hr. at room temperature ranging from 15° to 20° C. Brownish necrotic spots, similar to those induced by spore infection, were clear on the four varieties. In addition to the necrotic symptoms, cut shoots showed wilting and twisting, and they became dark green in colour. Necrotic lesions, which appeared due to the toxic action of the filtrate, had almost the same size in the four varieties, denoting that the resistant, as well as the susceptible, varieties of barley responded similarly to the toxic action of *Helminthosporium* filtrate. It was also possible to reproduce symptoms of oat blight by using the culture filtrate of *Helminthosporium victoriae*[4]. Dilution of the filtrate with water 1 : 100 did not affect symptom reproduction, while filtrate diluted to 1 : 1,000 failed to reproduce symptoms on any of the barley varieties.

During 1958–1959 pathogenicity of the Dutch strain of *Helminthosporium sativum* to the Egyptian barley variety Baladi 39 and to the Sudanese variety Baladi was tested. The two varieties proved to be moderately susceptible to infections by *Helminthosporium* spores. The degree of susceptibility of both varieties was more or less comparable with that of the Dutch variety Agio. When cut shoots of the Egyptian variety Baladi 39 and the Sudanese variety Baladi were dipped in *Helminthosporium* filtrate, prepared exactly under the conditions mentioned, the shoots wilted, twisted and became darker in colour, but no necrotic symptoms could be detected at all. Hence, reproduction of natural symptoms on these African varieties was unsuccessful by using the filtrate of the Dutch strain of *Helminthosporium sativum*. Such differences between symptom production by the fungal pathogen and symptom reproduction by its filtrate emphasize the specificity of the host variety on which natural symptoms can be reproduced. Further work on this point in which African strains of *Helminthosporium* are involved, and on the nature of the toxins produced by the fungus, is in progress, and full details will be published later.

Effect of Excess Supply of Heavy Metals on Barley during Germination, with Special Reference to Catalase and Peroxidase

The injurious effect of the excess supply of heavy metals on plant growth, among other factors, has been attributed to induced iron-deficiency[1–3]. Recently[4–7], it has been shown that heavy metals such as cobalt, nickel, copper, molybdenum and chromium, when supplied in excess, depress chlorophyll and catalase; in some instances peroxidase is also depressed. The repeated application of iron–ethylenediamine tetra-acetic acid to plants receiving the heavy metals mitigates the effect of heavy metals[6] on chlorophyll, catalase and peroxidase.

In order to test the effect of heavy metals on catalase and peroxidase before chlorophyll had developed, some preliminary investigations were made on barley (*Hordeum vulgare*) and 'kharbooza' (*Cucumis melo*) during germination. Contrary to the results obtained with adult plants, in seedlings the synthesis of catalase seemed to be stimulated at 1 m*M* concentration of cobalt. The investigation was extended to other heavy metals, and the effect of cobalt, nickel, molybdenum and chromium supply, each at 1, 5 and 25 m*M* concentrations, on barley during germination was studied. Each of the excess heavy-metal treatments was superimposed on a basal solution[6]—the full nutrient solution. The seeds were soaked in the appropriate nutrient solution for 12 hr. and then transferred to Petri dishes containing filter paper liberally moistened with the solution in which the seeds had been soaked. The Petri dishes were maintained in diffused light at room temperatures which varied between 19° and 23° C.

Table 1. Effect of the Excess Supply of Heavy Metals on Germination and Catalase and Peroxidase.
Results expressed as percentage increase (+) or decrease (−) over values obtained with seedlings given basal solution (ref. 6)

Treatment		Catalase		Peroxidase		Germination (length of first formed root)
		a	*b*	*a*	*b*	
Cobalt	1 m*M*	+44	+53	−20	−15	+21
	5 m*M*	+53	+33	−11	−22	−35
	25 m*M*	+61	−10	−39	−64	−92
Nickel	1 m*M*	+30	+24	−6	−10	−27
	5 m*M*	+147	+61	−21	−49	−77
	25 m*M*	+105	+24	−64	−78	−96
Molybdenum	1 m*M*	+2	+27	−7	+13	+1
	5 m*M*	+25	−25	−11	−47	−86
	25 m*M*	−22	−57	−57	−76	No emergence
Chromium	1 m*M*	+36	−3	−28	−49	−89
	5 m*M*	+152	+35	−47	−72	−96
	25 m*M*	+112	+26	−71	−76	No emergence

a, Expressed on fresh weight basis; *b*, expressed on per-seedling basis

At 1 m*M* supply germination was slightly stimulated by cobalt and depressed by nickel and chromium. At 5 m*M* and 25 m*M* concentrations germination was depressed by cobalt, nickel, molybdenum and chromium.

There was active synthesis of catalase during germination—eight-fold increase in 120 hr. from the soaking of the seeds in the basal solution. Excess supply of cobalt, nickel and chromium stimulated the synthesis of catalase, the effect being very marked at 5 and 25 m*M* supply each of nickel and chromium. No stimulation of the synthesis of catalase was found with molybdenum at 5 and 25 m*M* concentrations. In the germinating seeds, the main region for the synthesis of catalase was the growing embryo, that is, the developing root and shoot tissue. At 5 and 25 m*M* supply of nickel and chromium, although the formation of catalase-synthesizing tissue was severely restricted, yet the catalase expressed on the per seed basis was found to be higher than in seedlings raised without the excess supply of heavy metals.

As compared with catalase, peroxidase synthesis was slow—less than two-fold increase in 120 hr. from the soaking of seeds in the basal solution. Excess supply of heavy metals depressed peroxidase. Uptake of oxygen by the seedlings, as measured in a Warburg apparatus at 32° C., and total dehydrogenase activity, as measured by the reduction of triphenyl-tetrazolium chloride, were also depressed by the heavy metals, the effects being more pronounced in the growing embryo than in the rest of the seedling.

The uptake of heavy metals continued even when the germination was severely depressed and in general the heavy metals depressed the uptake of iron.

The stimulation of the synthesis of catalase by the excess supply of heavy metals would mean not only the increased synthesis of the protein moiety of catalase but also increased synthesis or at least availability of iron-porphyrin for the formation of catalase. This result cannot be explained in terms of the hypotheses advanced to date to explain the role of the excess supply of heavy metals in plants.

NEW VERSATILITY IN Liquid Scintillation Counting

With the Packard Tri-Carb® Spectrometer

Now you can count assortments of carbon-14 and tritium samples interchangeably without readjusting controls . . . perform double labeling at the true balance point for each isotope . . . or do both. In addition, the new Tri-Carb Spectrometer with its expander-amplifier circuitry can be used for dual-channel gamma counting merely by adding a well detector. This versatility is a Packard exclusive—made possible by two separate channels of pulse height analysis with individually variable amplifiers and four adjustable discriminator levels.

Other features are all-transistorized circuitry and convenient mounting of all controls at eye level above the freezer. Width of the instrument is reduced to a space-saving 3½ feet.

Three models in various combinations offer a total of nine liquid scintillation counting systems—refrigerated or non-refrigerated . . . for automatic or semi-automatic operation. From this selection you can readily meet the requirements of your budget and provide for present and future needs. You'll get the satisfaction and performance which only a Tri-Carb Spectrometer—with its world-wide reputation for accuracy and reliability—can provide. Call your Packard representative or write for Bulletin AD-1002.

ENTOMOLOGY

An Abnormal Form of Female Rat Flea, *Xenopsylla cheopis* Roths.

Rothschild, in 1911, separated the three species of fleas, *X. cheopis*, *X. astia* and *X. brasiliensis* of the genus *Xenopsylla* found on rats. *X. cheopis* is widely distributed in the tropics and is the principal plague flea in India. The three species (♀♀) mentioned here can be easily identified by the shape of the spermatheca. Until now, it has been reported that *X. cheopis* has a single spermatheca[1-3] (Fig. 1).

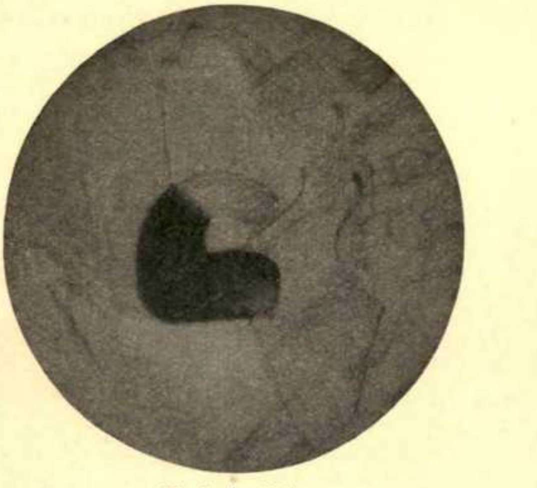

Fig. 1. (× 132)

During a routine collection of rat fleas from Delhi City for conducting insecticide susceptibility tests, a single specimen of *X. cheopis* (♀♀) was observed which has the normal typical spermatheca and another spermatheca-like structure (Fig. 2). The normal spermetheca has all the characteristics of a typical specimen: (1) the tail is much longer and at the base it is slightly wider than at the head; (2) the terminal part of the tail is longer and narrows gradually; and (3) the lower margin of the head and tail-end are at about the same level (Fig. 2, *A*). The additional spermatheca-like structure (the tail-end of which is just close to the terminal part of the tail of the typical form (Fig. 2, *B*) is pear-shaped and has a small blunt tail, but no distinct head portion.

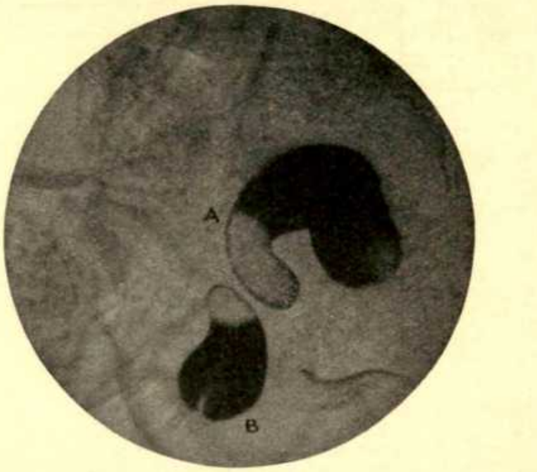

Fig. 2. (× 132)

There has been no previous record in the literature, so far as we know, of the occurrence of a similar abnormality in *X. cheopis* (♀♀).

MICROBIOLOGY

Role of the Pentose Phosphate Pathway in *Pasteurella multocida*

It is acknowledged that in a large number of bacteria the main path for carbohydrate oxidation is the pentose phosphate cycle or other metabolic sequences not involving the Embden–Meyerhof pathway[1]. In the genus *Pasteurella*, work on *P. pestis* has shown that growing cells oxidize glucose through the pentose phosphate pathway[2], but resting cells oxidize glucose through the combined action of glycolysis and the citric acid cycle[3]. In contrast with this metabolic duality, in *P. multocida* the pentose phosphate cycle is the main path for carbohydrate oxidation, both in growing and resting cells, and in regard to the citric acid cycle its principal role seems to be to supply carbon skeletons for the synthesis of amino-acids. These conclusions are borne out by experiments carried out with *P. multocida* (strain Beaufort No. 28 from the Institut Pasteur cultured aerobically for 4 hr. (growing cells) or 24 hr. (resting cells)) at 37° and *p*H 7·2 in a medium made of meat extract, 5 gm.; yeast extract (Difco), 1 gm.; peptone, 30 gm.; sodium chloride, 5 gm.; glucose, 20 gm.; agar, 25 gm. and water up to 1 litre. Our observations can be summarized as follows.

(*a*) Resting *P. multocida* oxidizes glucose, fructose, gluconate and ribose. The Qo_2 values (μl. oxygen consumption/mgm. dried cells/hr.) of the cells incubated with 5 m*M* substrate, in m*M* phosphate buffer *p*H 7·2 at 37°, were 24 with glucose or fructose, 18 with gluconate and 12 with ribose (control, 2·3–2·6).

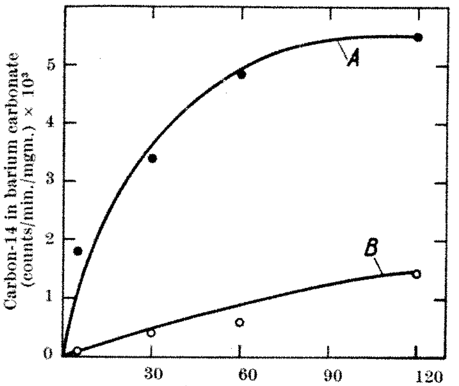

Fig. 1. Radioactivity of carbon dioxide evolved during the oxidation of [1-^{14}C] and [6-^{14}C] glucose by *P. multocida*. Incubation in double side-arm Warburg manometers. 23·2 mgm. (dry weight) of bacterial cells suspended in m*M* phosphate buffer, *p*H 7·2 with 5·3 m*M* [^{14}C] glucose (3·70 × 10^6 counts/min.); total volume, 2·65 ml.; 0·15 ml. 2·7 *N* potassium hydroxide in the centre well and 0·20 ml. 3 *N* sulphuric acid in one side-arm; air in the gas space; temperature, 37°. At the intervals stated, the acid is tipped into the main compartment of the flask and the incubation continued for 15 min. The carbonate fixed in the alkali is precipitated as barium carbonate for carbon-14 counting as described previously (ref. 5). Line *A*, [1-^{14}C]-glucose; line *B*, [6-^{14}C] glucose. Qo_2, 22·2; control (without glucose), 1·3

(*b*) The specific activity of the carbon dioxide produced by oxidation of [1-^{14}C] glucose with resting cells of *P. multocida* is much higher than with [6-^{14}C]-glucose (Fig. 1). An approximate evaluation of the contribution of the pentose phosphate cycle to glucose oxidation can be calculated[4] by extrapolating to zero time the ratio of the specific activities of the carbon dioxide produced from [6-^{14}C] glucose and [1-^{14}C] glucose, respectively. From the results shown in Fig. 1, about 85 per cent glucose should be oxidized through the pentose phosphate cycle. With growing *P. multocida* the results are similar.

(*c*) After oxidation of carbon-14 glucose (1, 6 or *G*) by resting or proliferating *P. multocida*, the cells incorporate carbon-14. Paper chromatography and radioautography of methanol–water extracts[5] of the cells show the labelling of: (1) glucose, glucose-6-phosphate, fructose-1,6-diphosphate, 6-phosphogluconate, ribose-5-phosphate, and sedoheptulose-7-phosphate; (2) lactic, succinic, fumaric and malic acids; and (3) glutamic and aspartic acids, alanine, threonine, leucine, tyrosine and valine-tryptophan.

During the oxidation of [6-^{14}C] glucose by resting *P. multocida*, the kinetics of distribution of carbon-14 (per cent) in the sugar phosphates (and glucose) fit into the pattern of the shunt pathway. In fact, in the 0–3 min. interval, carbon-14 appears in the sugar phosphates in the order (1) glucose-6-phosphate, (2) 6-phosphogluconate and (3) ribose-5-phosphate, sedoheptulose-7-phosphate and fructose-1,6-diphosphate. After incubation for 3 min., variations in 6-phosphogluconate, ribose-5-phosphate and sedoheptulose-7-phosphate run closely parallel. On the other hand, the percentage of carbon-14 in glucose remains nearly constant. With [1-^{14}C] glucose as substrate, glucose-6-phosphate and 6-phosphogluconate again are labelled first, but the percentage of carbon-14 in the glucose reservoir decreases very rapidly. Similar kinetics are found with growing cells.

(*d*) In the presence of radioactive bicarbonate, gluconate oxidation promotes fixation of carbon-14 by resting *P. multocida*. It appears in glucose-6-phosphate, as would be expected from the reversibility of 6-phosphogluconate decarboxylation[6].

(*e*) Resting *P. multocida* oxidize pyruvate and the intermediates of the citric acid cycle. With substrate concentration 10 m*M*, the Qo_2 values (measured as in *a*) were 24 (pyruvate), 3·7 (citrate), 6·2 (DL-isocitrate), 19 (α-oxoglutarate), 26 (succinate), 13 (fumarate), 5 (L-malate) and 3·5 (control). After oxidation of [2-^{14}C] pyruvate, carbon-14 appears in the carbon dioxide evolved, the intermediates of the citric acid cycle and amino-acids. Growing cells incorporate more carbon-14 into the amino-acids (Table 1). It is to be noted that the labelling of cysteic acid shows that the bacterium is able to fix sulphur into organic substances.

Table 1. DISTRIBUTION (PER CENT) OF CARBON-14 IN AMINO-ACIDS AFTER OXIDATION OF [2-^{14}C] PYRUVATE BY *P. multocida*

Growing cells: 65 (initial) and 78 (final) mgm. *P. multocida* (dry weight) suspended in 22·4 ml. culture medium (see text) with 25·2 μmoles [2-^{14}C] pyruvate (17·76 × 10^7 counts/min.).
Resting cells: 142 mgm. bacteria suspended in 10 ml. m*M* phosphate buffer, *p*H 7·2, with 112 μmoles [2-^{14}C] pyruvate (8·8 × 10^7 counts/min.). Temperature, 37°. After 60 min. incubation, the suspensions were spun off and the cells suspended in 9 ml. methanol for paper chromatography, radioautography and carbon-14 counting (ref. 5).

Amino-acid	Carbon-14 fixed (percentage of total in the methanol–water soluble substances) Growing cells	Resting cells
Aspartic	0*	0·3
Glutamic	2·5	3·3
Alanine	5·6	0·4
Serine	2·1	0·3
Glycine	1·6	0·6
Threonine	6·6	0
Histidine	5·3	0
Lysine–Arginine	5·3	0·7
Leucine	2·8	0·2
Tryptophan–valine	6·0	0
Cystine	0	0·2
Cysteic	0	11·6

* Not detectable on the radioautogram.

In proliferating *P. pestis*, the shunt pathway provides pentose phosphates for nucleotide synthesis[3], and this can also be readily accepted in *P. multocida*; on the other hand, the pentose phosphate cycle also has a synthetic role in resting *P. multocida* as source of the pentose and heptose components of the polysaccharides of the bacteria[7].

Spontaneous Development of *L* Forms of Streptococci requiring Secretions of Other Bacteria or Sulphydryl Compounds for Normal Growth

CERTAIN strains of non-hæmolytic streptococci, isolated in our laboratory from blood cultures of cases of subacute bacterial endocarditis and from otitis media, were found to require for their growth a substance secreted by most bacteria. They were isolated only due to the incidental presence of

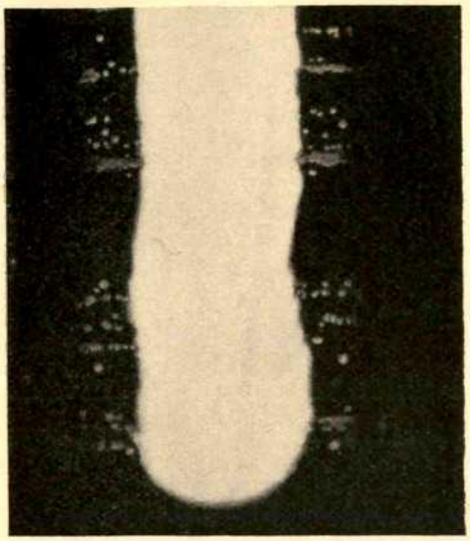

Fig. 1. Incomplete satellite growth zone of *Streptococcus* 6626. (Polarized light. × 5)

colonies of contaminating bacteria, around which they grew in satellite colonies. The bacterial secretion could be replaced by some sulphydryl compounds. In the absence of such substances, these strains tend to spontaneous development of *L* forms if an appropriate osmotic stabilizer is present in the agar medium. The sulphydryl compounds as well as the bacterial secretion seem to play a part in the formation of the cell wall of these streptococci.

The zone of satellite growth of the strains as shown on plates of *B.B.L.* soy trypticase agar or Difco heart infusion agar containing 5 per cent serum differed significantly from that known from *Haemophilus influenzae*, being much narrower and ending with a rather sharp edge (Fig. 1) which was accentuated if by incubating for a further 24 hr. the unused nutrients of the surrounding agar medium caused the outer colonies to grow in size.

A great variety of bacteria—Gram-positive and Gram-negative, catalase-positive and catalase-negative—including bacteroides, as well as actinomycetes and yeasts promoted growth.

The first substance found to be capable of substituting for the bacterial secretions was cysteine in concentrations of 0·5–1 mgm./ml. Its growth-promoting influence could not be explained by change of redox potential only, as anaerobic conditions did not alter the growth requirements of the strains.

Sodium thioglycollate, reduced glutathione and thiomalic acid were effective. Cystine, cysteic acid, methionine, sodium thiosulphate (up to 1 mgm./ml.) and elementary sulphur were not effective. It was therefore concluded that growth promotion by those substances depends on the sulphydryl groups.

The morphology of the streptococci was normal if growth was optimal. With lower concentrations of sulphydryl group substances, or at the outer limit of the satellite growth zone, the cocci showed extreme pleomorphism with swellings, global forms and elongations of different degrees. This suggested that the substance secreted by other bacteria, or the cysteine and like substances, had some function in the formation of cell walls, and that growth in *L* colonies might be produced without growth-promoting substances if support were given by adding to the medium substances known to have an osmotically stabilizing effect on bacterial cells the wall of which developed incompletely or not at all.

On plates of heart infusion agar + 5 per cent pooled human serum + 2 and 5 per cent sucrose respectively, two of the streptococcal strains grew in typical *L* colonies. The addition of sucrose to the medium had a remarkable influence also on the satellite growth of the streptococcus. Satellite colonies farther off were gradually diminished in size down to small transitional colonies, containing normal streptococcal forms together with swollen forms and net-like structures. Still farther off, beyond the influence of the bacterial secretion, there was pure growth of typical *L* colonies (Figs. 2 and 3). Many of these *L* forms remained stable even in the presence of other bacterial colonies or of cysteine.

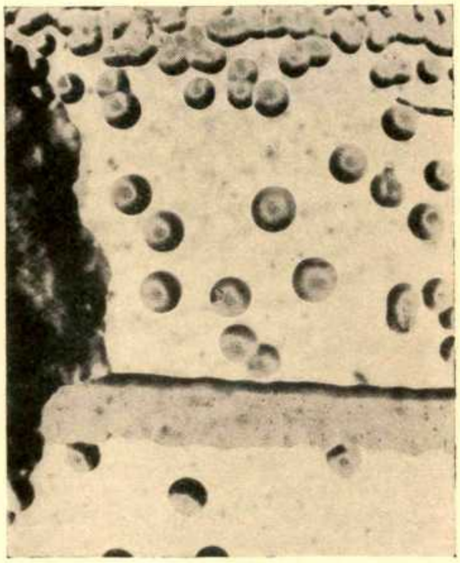

Fig. 2

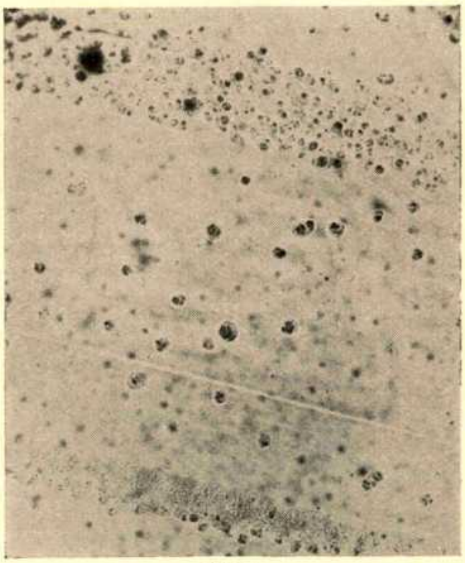

Fig. 3

Figs. 2 and 3. Development of normal satellite colonies (near growth of *E. coli* (Fig. 2) and of *L* colonies (beyond influence of bacterial secretion) (Fig. 3) from the same plating of *Streptococcus* 3554 on heart infusion agar containing 5 per cent human serum and 2 per cent sucrose. (× 35)

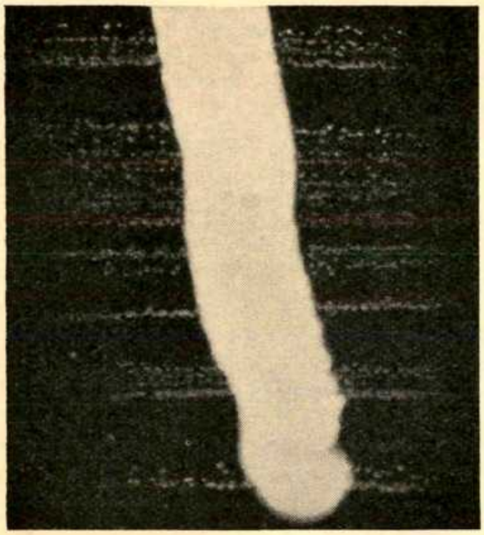

Fig. 4. 'Normalized' satellite growth zone of *Streptococcus* 6626 obtained under anaerobic conditions. (Polarized light. × 5)

Another of the streptococcal strains described here did not produce typical *L* colonies if sucrose was used as stabilizer, but in the presence of 1·5 per cent sodium chloride it grew colonies consisting of 'large bodies', swollen forms not stained by the Gram technique, and net-like structures.

A fourth strain also did not grow in typical *L* colonies, but on either of these media colonies developed which may be described as transitional stages containing a mixture of globular forms, swollen and elongated cocci stainable by the Gram technique, and of net-like structures. Possibly we have not yet found the appropriate osmotic stabilizer for the support of the *L* forms of these two strains.

Only living bacteria had an effect in promoting growth. The secreted substance passed through 'Cellophane'. It lost its growth-promoting property rapidly by oxidation. Obviously it was this lability which accounted for the abnormal appearance of the satellite growth zone, the growth-promoting substance losing its activity while diffusing into the more distant parts of the agar. Under anaerobic conditions, satellite colonies developed not only in a zone much broader than that obtained aerobically but also gradually diminished in size in the outer parts of the zone (Fig. 4).

Cysteine (1 mgm./ml.) or other sulphydryl compounds are known to be essential for growth from small inocula of hæmolytic streptococci[1]. Although our strains require cysteine even for growth from large inocula, basically the requirement might be the same. Nickerson and van Rij[2] found that sulphydryl compounds promoted cell division.

The effect of penicillin in inducing growth of *L* forms and the resistance of *L* forms to penicillin is well known. According to Dufrenoy and Pratt[3], penicillin inhibits the reduction of —S—S bonds of the bacterial cell constituents, whereas cysteine is known as a neutralizer of penicillin[4]. Nickerson[5] showed that a mutant of *Candida albicans* lacking an enzyme capable of reducing —S—S bonds of the cell wall grew in filaments instead of growing in the yeast form.

In our strains it may be assumed that we are dealing with an inability to reduce —S—S bonds required for the formation of the cell wall as a genetic metabolic defect, which is not necessarily lethal if appropriate stabilizers are present enabling them to continue life as *L* forms. There is an obvious analogy to the *L* form which Lederberg and St. Clair[6] succeeded in obtaining in sucrose agar from a mutant of *E. coli* deficient in diaminopimelic acid.

The possibility of using the specific growth requirement of these streptococci for development of a bioassay for sulphydryl groups is being studied.

Specificity of the Mutagenic Action of the Alkylating Agents

ETHYL methanesulphonate is mutagenic when applied to mature bacteriophage particles in suspension[1]. Methyl methanesulphonate is either non-mutagenic or results in the induction of mutants at a frequency not much greater than the spontaneous frequency[2]. Krieg (quoted by Bautz and Freese[2]) has reported that ethyl methanesulphonate will not induce reversion of bacteriophage mutations induced by itself. Mutants induced by ethyl methanesulphonate can be induced to revert with 2-aminopurine[2]. Methyl methanesulphonate is much more lethal on a molar basis than is the ethyl derivative[1].

Freese accounts for the specificity of the ethyl derivative by supposing that both ethyl and methyl methanesulphonates combine with guanine residues within the deoxyribonucleic acid (DNA), but that only the ethylated guanine breaks down to form an apurinic acid at an appreciable rate. The apurinic acid is assumed to lead to errors in pairing, resulting in mutation during vegetative growth of phage.

Treatment of bacteriophage *T*2 with ethyl methanesulphonate labilizes the phage, so that the number of plaque-forming units diminishes when the treated phage is stored in the absence of the alkylating agent[1]. It is implied by the Freese hypothesis (but is not essential to it) that this post-treatment decay in plaque-forming units represents the progressive depurination of the alkylated DNA.

I have found, in confirmation of earlier results[1], that treatment of bacteriophage *T*2 with methyl methanesulphonate results in a post-treatment decay effect comparable to that induced by ethyl methanesulphonate. The degree of decay after treatment depends on the initial concentration of the alkylating agent used for treatment (Fig. 1). The methyl methanesulphonate effect occurs at a lower molarity but at a higher immediate inactivation than does the ethyl methanesulphonate effect. Treatment of bacteriophage with alkylating agents causes both an immediate and a delayed decrease in plaque-forming centres and may result in an appreciable frequency of induced mutation, depending on the agent. In this

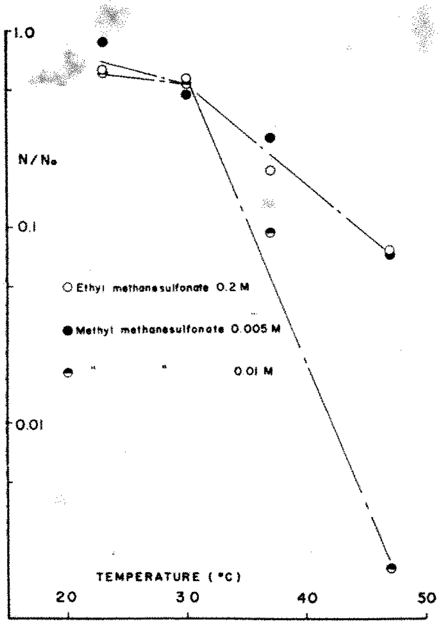

Fig. 1. Post-treatment decay of bacteriophage *T*2 following treatment with alkylating agents.
Approximately 10^{12} phage per ml. were incubated in *M*-9 buffer with the indicated alkylating agent for 40 min. at 37° C. The survivals immediately following treatment were: non-treated, 1·0; 0·2 *M* ethyl methanesulphonate, 0·97; 0·005 M methyl methanesulphonate, 0·57; 0·01 *M* methyl methanesulphonate, 0·16. Following treatment, the suspension was diluted by a factor of 10^3 with *M*-9 buffer and samples were stored 21 hr. at the temperatures indicated. All values are corrected for the decay of non-treated material kept at the same temperature. Plaque-forming centres were determined by the agar layer method. The results are not plotted as an Arrhenius curve in order to indicate lack of a theoretical interpretation for the concentration effect

experiment the frequency of *r* plus mottled mutants in the material treated with ethyl methanesulphonate was about 7×10^{-3} immediately after treatment, 8×10^{-3} after 21 hr. at 30° C. and 6×10^{-3} after 21 hr. at 47° C. This frequency was five times the spontaneous. The number of mutants scored was so small that the frequency of mutants in the material treated with methyl methanesulphonate was not significantly different from the spontaneous frequency. In all parts of the experiment, 20 mutants per 19,000 total plaques were scored in the non-treated set, 89 per 17,000 plaques in the set treated with ethyl methanesulphonate, and 9 per 12,400 and 19 per 15,000 plaques in the sets treated with 0·005 *M* and 0·01 *M* methyl methanesulphonate, giving frequencies of 1·0, 5·2, 0·7 and $1·3 \times 10^{-3}$ respectively.

Table 1. EFFECT OF METHYL METHANESULPHONATE IN INDUCING REVERSIONS OF *E. coli WP*-2

Treatment	Fraction surviving determined on: Minimal + tryptophan	Fraction surviving determined on: Minimal + 2·5 per cent broth	Total revertants per ml.*	Revertants/ 10^8 survivors
None	1·0	1·0	60	13
Ethyl methane-sulphonate (0·1 *M*)	0·87	0·87	3,120	780
Methyl methane-sulphonate				
0·025 *M*	0·43	0·5	710	308
0·05 *M*	0·0005	0·0096	150	3,400

* Revertants were scored after 2 days incubation at 37° C. on plates of minimal medium agar supplemented with 2·5 per cent Difco nutrient broth (8 gm./l.). Treatment was for 30 min. in 0·1 *M*, *p*H 7·2, phosphate buffer. The cells were collected and washed from exponentially growing cultures in minimal medium plus tryptophan before treatment and then collected, washed and re-suspended in buffer following treatment.

There were $4·6 \times 10^8$ viable organisms per ml. in the non-treated sample.

Methyl methanesulphonate is highly mutagenic for the tryptophan-requiring *WP*-2 derivative of *E. coli* strain *B*/*r* (Table 1). An increased frequency of both large colonies (presumed revertants) and small colonies (presumed suppressors) results from treatment with this alkylating agent. The frequency is comparable with that induced by ethyl methanesulphonate. Methyl methanesulphonate causes an effect similar to that of ultra-violet irradiation of *B*/*r*, since treated bacteria give higher viability counts on medium supplemented with broth than on a synthetic medium[3]. There seems to be no post-treatment decay effect in bacteria comparable to that observed with bacteriophage[4]. It is known that in *Neurospora* dimethyl sulphate is even more effective as a mutagen at certain loci than is either diethyl sulphate or ethyl methanesulphonate[5].

I conclude, therefore, that the post-treatment decay reaction following treatment of bacteriophage with alkylating agents is not directly related to the mutagenic reaction, and that either the mechanism of the mutagenic action of alkylating agents differs in mature bacteriophage from that in bacteria, or that the specificity of the ethyl derivatives for bacteriophage mutagenesis is not completely explained.

This investigation was supported in part by a research grant from the National Institutes of Health, U.S. Public Health Service.

SOIL SCIENCE

Resistance of Humus to Decomposition

AN organic soil (previously under wattle followed by grass) containing 8·51 per cent organic carbon (Walkley and Black[1], corrected) has been submitted 204 times to the following cycle: (*a*) moistened to field capacity; (*b*) allowed to decompose for 5 days at 25° C. in the macro-respirometer[2]; (*c*) oven-dried at 100° C. for 48 hr. After 105 such treatments it was calculated[3] that no further decomposition would occur, on moistening, after about the 250th treatment and that 73 per cent of the organic carbon originally present would have been mineralized. After 204 such treatments, however, the soil had become completely structureless and on moistening formed cohesive lumps, a condition adverse to aerobic decomposition. The experiment was therefore concluded and the soil analysed. A comparison of the results for the soil before and after the 204 treatments is given in Table 1.

The agreement between the calculated value for carbon mineralization after 250 treatments (73 per cent) and that found after 204 treatments (63·5 per cent) is satisfactory, particularly since the calculated value (based on the first 105 treatments) did not allow for the subsequent loss of structure during the later treatments, leading to decreased microbial activity and mineralization of organic carbon.

The main feature of interest is the high proportion of organic carbon and nitrogen that remained un-

Table 1

	Before	After	Mineralized (per cent)
Organic carbon (per cent)	8·51	3·11	63·5
Organic nitrogen (per cent)	0·69	0·37	46·4
C : N ratio	12·33	8·41	
*p*H (using 0·01 *M* calcium chloride)	6·0	7·9	
p.p.m. inorganic phosphorus (cold *N* sulphuric acid)	133	570	
p.p.m. organic phosphorus (Walker and Adams, ref. 4)	437	Nil	100·0

mineralized in spite of the enhanced microbial activity following the frequent moistenings of the soil after oven-drying. This is in marked contrast to organic phosphorus, which was completely mineralized. Thompson and Black[5], however, have shown that soil organic phosphorus is susceptible to hydrolysis with hot water. A duplicate soil sample was therefore kept at field capacity at 100° C. for 16 days (a period equivalent to that in which the experimental soil was in a hot moist state during its 204 treatments) when it was found that 53 per cent of the organic phosphorus and 7 per cent of the organic nitrogen were hydrolysed, with no increase on longer heating. With the experimental soil, therefore, the non-hydrolysable organic phosphorus compounds must have been microbially decomposed together with at least part of the hydrolysable compounds which are likely to be even more susceptible to microbial attack. It appears that potentially the whole of the soil organic phosphorus is fairly readily decomposable microbially. Since organic phosphorus complexes of soil are more readily extracted than other fractions of soil organic matter[6] they may also be more accessible to micro-organisms.

The increase in *p*H probably results from the release of bases during decomposition and the absorption of carbon dioxide by the sodium hydroxide in the respirometer vessel, which would prevent the formation of carbonic acid. The increase in ammonia amounted to only 1 m.equiv./100 gm. soil instead of the 23 m.equiv. demanded by theory. Presumably much of the ammonia was driven off under the hot, moist slightly alkaline conditions occurring early in the successive drying periods.

PSYCHOLOGY

Effect of Attention in Peripheral Vision

The facts adduced by B. Babington Smith[1] appear to be new. At first it seemed that they might be explained in terms of what Stout calls "the conditions of attention"[2]—conditions that include change as well as extensity, intensity, duration, contrast and interest. If Stout is right, the factor missing in the object was change. I therefore repeated the experiment with objects containing moving parts, like the second-hand of a watch and an oscillating compass needle, and was amazed to find that the peripheral fade-out was, if anything, more marked.

The explanation of the phenomenon is, I believe, the following. When one inhibits the natural tendency to focus an object to which one is attending, one inevitably tends to reconstruct its details from memory. Though perception and memory are not inherently incompatible, the simplest kinds of image are, in fact, antagonistic to their sensational counterparts. Hence the effort to reconstruct the object from memory inhibits the exact perception of it. The most important inference to be drawn from the experiment is not that attention inhibits the perception of peripheral objects, but that the instinct of curiosity in its simpler forms operates by means of a commutative mechanism, whereby it automatically switches over to memory, when it is frustrated in perception. Experiments might be devised to show under what conditions the mind automatically switches back to perception, and, once the main facts had been elucidated, considerable improvements in methods of teaching and learning might be effected.

Arthur Thomson

c/o Dr. C. B. Robinson,
Purdysburn Hospital,
Belfast 18.

---

[1] *Nature*, **189**, 776 (1961).

[2] Stout, G. F., *Manual of Psychology*, fourth ed., 167.

In my communication of March 4, I spoke of placing objects on a table. As Mr. Thomson has deduced, the situation I described was static, and thus change, which is, broadly speaking, one of the essential conditions for perception, was lacking. Mr. Thomson's observations with the second-hand of a watch and a compass needle are very interesting but puzzle me, for I have failed to find what he describes. Others as well as myself have found that objects in motion do not disappear; though one correspondent has spoken of 'flicker', seen peripherally, disappearing when attended to.

The second part of Mr. Thomson's letter also puzzles me; while I can conceive that "the effort to reconstruct an object from memory inhibits the exact perception of it", it seems to me that switching over "by means of a commutative mechanism", as he suggests, ought to produce a memory image in place of the percept which disappears. This is not, however, what seems to happen.

Finally, Mr. Thomson writes that the facts I adduced appear to be new. Having failed to locate similar observations in Aubert[1], Baird[2] or Helmholtz[3], I had hoped this was so. Since publication, however, further search suggests that observations by Troxler[4], who was studying reports of a blind spot, and (according to Helmholtz's reference to their work) by Aubert and Förster[5], who were studying the sensitivity of the retina, refer to differential disappearance of objects in the peripheral field in a way conformable to what I have described.

Even nearer to the mark is a note by J. H. Hyslop[6], to which Prof. R. C. Oldfield has directed my attention, in which the following occurs: "When mentally preoccupied and having the eyes fixated on a given point or object I often notice the disappearance of a part of the indirect field of vision.

I have tried to see whether it might not be due to the falling of the object on the blind spot; but uniformly discover that it is not, as the disappearing object may be on the side of the retina opposite the blind spot. On careful experiment and observation I find that the disappearance is directly related to the degree of abstraction, and that I can reproduce it artificially, if I am successful, as I sometimes am, in effecting the abstraction necessary and at the same time the proper adjustment of attention. It is difficult to produce the artificial abstraction required, but when I am successful I effect the disappearance of the object, which immediately reappears the moment attention is given to it without altering the fixation of the eyes. The effect seems to be that of making clear an actual impression, while attention in the previous experiment seems to destroy an after image."

Hyslop's use of the term 'abstraction' in contrast with 'attention' is interesting, and supports the view of several correspondents, particularly Dr. N. Moray of Sheffield, that the word 'attention' in my communication in *Nature* is a source of difficulty. It was of course with this possibility in mind that I had written "attend to one of the objects and try to see or describe it in detail".

Prof. O. L. Zangwill has suggested that the mechanism of disappearance is related to Hering's local adaptation, but while this may be so, I find no evidence of Hering having associated local adaptation with attention.

Centrally Produced Geometrical Illusions

So little is known about the mechanism responsible for the well-known geometrical illusions that it is not possible to decide on general theoretical grounds whether they are the result of retinal processes, central processes or both. An experimental procedure to demonstrate that they are at least partly of central origin is therefore of interest.

The procedure consists of constructing a visual target, in which the illusion figure is seen in stereoscopic vision but not in monocular vision. The simplest way of achieving this is as follows. A sheet of glass is covered with an array of randomly placed dots. On a second glass sheet the well-known Müller–Lyer illusion, for example, is constructed out of dotted lines, the separation of the dots being about the same as those on the first sheet. The two are then mounted parallel to one another, separated by a few inches. When viewed monocularly under conditions which prevent head movements, shadows and other sources of monocular distance clues, the two planes are seen as merged and the Müller–Lyer figure cannot be distinguished. In binocular vision the two planes are easily separated and all subjects report the illusion.

The rigour of the experiment can be improved in two ways: (1) if the three vertices A, B, C, of the figure are marked by dots of a different colour, judgment of distance AB compared with distance BC can be made, and in fact turns out to be significantly different, under monocular and binocular conditions; (2) instead of using two real planes, the situation can be simulated by constructing stereoscope diagrams using an electronic computer[1]. This enables a rigorous control of factors such as dot density, and ensures that the signal received by each eye is a thoroughly pseudo-random array of dots; the information used by the stereoscopic mechanism is entirely contained in the relation between the two arrays.

A quantitative comparison of illusions produced in this way with their more familiar form involves intricate statistics and will be reported elsewhere. Figural after-effects can be produced under similar conditions, but are always weak, though I believe that this is due to incidental aspects of the procedure.

The work described here is part of the research programme of the National Physical Laboratory and this communication is published by permission of the Director of the Laboratory.

MISCELLANY

The National Reference Library of Science and Invention

THE leading article in *Nature* of July 1 presents a timely challenge to all organizations concerned with the use of scientific and technical knowledge to think deeply about the plans for the National Reference Library of Science and Invention. This is certainly a project needing imaginative and sympathetic consideration, not only by librarians but also even more, perhaps, by the scientific societies and institutions and by technical interests in industry. It is earnestly to be hoped that, as representatives of potential users of the new library, they will study the plans and give their considered views soon, lest the preparatory work becomes too far advanced for them to be taken into account.

The success of the undertaking will, however, depend primarily on the degree to which the Government itself demonstrates its determination to treat the communication of research results, and technical knowledge generally, with the same seriousness and sense of urgency as are devoted to the acquisition of them. In this, the new Library could prove a most potent instrument. But on its two fundamental needs—adequate space to house the necessary documents and adequate staff to exploit them—Mr. Freeth's reply to the adjournment debate in the House of Commons on March 14 was anything but reassuring. The decision to split the holdings of the new Library between the British Museum site in Bloomsbury and the new building on the South Bank, while regrettable, is understandable. But it can only be regarded as a workable compromise on two conditions: First, the South Bank building must be large enough to ensure that the bulk of the documents in frequent demand can be housed there, not only in 1965, but also for at least the following twenty years when, with the projected development of the Bloomsbury site, the situation might well be reviewed; and, secondly, arrangements must be made rapidly to transport or transmit documents held in the British Museum, so that the reader on the South Bank can have what he wants within minutes rather than hours. Much of the work of a reader in a reference library involves consulting many documents in conjunction with each other, and following up references found in them: delay in obtaining documents may make it impossible to complete a search and necessitate further visits. The obvious way to minimize this danger is to accommodate the greatest possible stock on the South Bank, and it is earnestly to be hoped that some way of increasing the space available will be found.

The Government seems to recognize that the new Library will ultimately need a staff which is well equipped professionally, particularly with scientists, and more numerous; but it is not enough to promise more staff when the Library becomes operational. In a lending library, records can give a reliable indication of users' habits; but virtually nothing is known as established fact about the use of reference material on open shelves. Surely now is the time to appoint a nucleus of the future staff, free of operational duties, to determine users' needs and to establish data on which detailed plans can be based.

Mr. E. M. Nicholson is doubtless wise to urge that now that a start has been made one should not jog the arm which lifts the cup. No one in his senses would wish to do so; the project must be given every chance to succeed. This means not only that critics should criticize constructively, but also that the Government should provide powerful support for the practical implications of its own proposals. Unless it does, the National Reference Library of Science and Invention may be little more than a less dingy Patent Office Library inconveniently and perhaps ineffectively linked with the British Museum.

LESLIE WILSON
(Director)

Aslib,
3 Belgrave Square,
London, S.W.1.

THE leading article in *Nature* of July 1, on the National Reference Library and other issues, calls for comment in regard to the problems of scientific information. Miss Webb is certainly to be supported in her aim of recruiting graduate staff who will assist readers in exploiting the resources of the new Library. The National Lending Library, which will not be in such direct contact with its users, is in a much more difficult position to assist in information retrieval (so long as it remains primarily a library). It is not to be expected, however, that such national libraries should undertake large tasks of information retrieval for readers, and hence they are not the correct authorities to handle research on the problems of the collation and dissemination of scientific information. Furthermore, although the needs of users must, of course, be studied and so far as possible met, the organization of such libraries is best left in the hands of scientifically trained librarians, and should not be considered a matter for dictation by any body of users who are only too often unable to specify their questions clearly and are mostly unacquainted with the intricacies of such problems as classification and information techniques. In some respects, however, this position may be changing, since an increasing proportion of the users of the Patent Office Library comprises information officers.

The problems of information retrieval arise mainly, however, in special libraries and, more particularly, in information departments in industry, research associations, and the like. Many smaller (and perhaps even some larger) researches into information techniques are being carried out, with little publicity, in information departments of the larger industries, and steady progress has been made by the Classification Research Group; most of such groups are in regular contact with Aslib. The collation of such work and the promotion of new researches would, therefore, be far better undertaken by Aslib, with its new research department, than put under the vague ægis of the national libraries. The research being undertaken by Mr. Cleverdon on retrieval by different methods of classification, at the College of Aeronautics, Cranfield, under the auspices of Aslib (on a grant from the National Science Foundation, and not, be it noted, from the British Government) is an excellent example of pioneering research in this field. The Advisory Council on Scientific Policy does not appear to be adequately acquainted with the nature of the problems to be solved.

Mr. Nicholson is quoted on the need for "senior people trained professionally both as scientists and librarians" and reference is made to the "perennial discussions on training intelligence and information officers". I would point out that the Institute of Information Scientists, formed in 1958, is now concerned with education in information work and a two-year postgraduate evening course, based on the Institute's full syllabus, was started last January at the Northampton College of Advanced Technology, London. Examinations based on this syllabus, and leading to the granting of its certificate, will be held by the Institute. The provision of this course was arranged in consultation with Aslib. If sufficient students are forthcoming, it is hoped to start a repeat course as early as next September. It may also be of interest to mention that Dr. G. Malcolm Dyson, now research director to *Chemical Abstracts*, served as president of the Institute for three years, and this office has now been undertaken by Sir Lindor Brown, who is also president of Aslib. The training of information scientists (the science graduate plus information officer really needed by Mr. Nicholson) is thus being actively and constructively promoted.

Finally, it needs to be stressed that information techniques and the problems of information retrieval, vital to modern scientific work, are not just matters of empirical trial and error, either in library organization or with complex computers, but require steady theoretical and practical scientific investigation. For this, the subject must ultimately become a recognized branch of postgraduate studies at universities and technical colleges. Much greater Government support and encouragement are necessary, however, before this final stage of respectability is achieved.

J. FARRADANE
(Honorary Secretary)

Institute of Information Scientists,
"Torran",
Crofton Road,
Orpington, Kent.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Spectroscopist (preferably with a degree in physics or chemistry, and experience in spectroscopy) in the Department of Chemistry, to have general responsibility for the maintenance and use of a range of spectroscopic equipment in the Department, including N.M.R., infra-red, Raman and U.V., and to collaborate with members of the teaching staff on research problems, and supervise routine measurements required—The Registrar, The University, Manchester, 13 (August 21).

Gordon Jacobs Fellow (with research qualifications) at the Royal Marsden Hospital for work in collaboration with the Institute of Cancer Research on the effects of ionizing radiations on nerves and the nervous system—The Secretary, Royal Marsden Hospital, Fulham Road, London, S.W.3 (August 25).

Sub-Librarian (graduate, with professional qualifications in librarianship) in the University Library—The Registrar and Secretary, The University, Bristol (August 25).

Assistant in Zoology in the Department of Natural History—The Secretary, The University, Aberdeen (August 31).

Assistant Lecturer or Research Assistant in Endocrine Biochemistry, to assist in the analysis of steroids and other hormones as part of the research programme of the unit—The Registrar, The University, Liverpool, quoting Ref. CV/N (August 31).

Assistant Librarian (with a good honours degree and preferably experience and professional diplomas)—The Librarian, University College of Sussex, Stanmer House, Stanmer, Brighton (August 31).

Horticultural Advisory Officers (with a degree in horticulture, agriculture or science, and preferably practical experience in the production of horticultural crops and in field advisory and experimental work) in the Agricultural Department, New Zealand, to advise growers chiefly on fruit and vegetable production, and to conduct field experiments, surveys and special investigations—The High Commissioner for New Zealand, 415 Strand, London, W.C.2, quoting Ref. B13/2/4 (August 31).

Lecturer (with a university degree or equivalent qualification) in the Department of Textile Chemistry—The Registrar, Manchester College of Science and Technology, Manchester, 1 (August 31).

Scientific Assistant, Abstractor (with a degree in agriculture or natural science, and able to read, or willing to learn, Russian)—The Director, Commonwealth Bureau of Pastures and Field Crops, Hurley, Berkshire (August 31).

Senior Lecturer (with a degree with honours in engineering, and preferably teaching experience) in Engineering; a Senior Lecturer (with an honours degree in mathematics and postgraduate qualifications and experience in university teaching) in Mathematics; a Lecturer (with an honours degree in mathematics and preferably some postgraduate study) in Mathematics; and a Lecturer (with an honours degree with special interest in inorganic and/or physical chemistry, and preferably experience in university teaching) in Chemistry at the University College of Townsville, University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (August 31).

Lecturer or Assistant Lecturer (medically or non-medically qualified candidate) in the Department of Histology—The Registrar, The University, Liverpool, quoting Ref. CV/N (September 4).

Graduate Research Assistant in the Department of Mechanical Engineering to work on problems of vibration and lubrication of machine tools—The Secretary and Registrar, The University, Southampton (September 9).

Chemists and Bacteriologists (with a degree in chemistry and bacteriology) in the Agriculture Department, New Zealand, for the investigation, analysis and research into dairy products, raw materials and allied by-products—The High Commissioner for New Zealand, 415 Strand, London, W.C.2, quoting Ref. B13/2/A (September 15).

Lecturer/Senior Lecturer in Horticulture at the University of Sydney, Australia, to undertake teaching and research in fruit and vegetable production—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 15).

Chemical Engineer, Physical Chemist or Physicist (honours graduate with at least two years' research experience) in the Unit Operations Group, Chemical Engineering Section, C.S.I.R.O., Melbourne, to be engaged on either of the following projects: (a) a study of the dynamic characteristics and controllability of closed circuit grinding, and other solid-handling processes, using modern techniques, including frequency response; or (b) investigations within the general field of water desalination—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 608/14 (September 16).

Principal Physicist (with a first- or second-class honours degree in physics) in charge of the Department of Medical Physics—The House Governor, King's College Hospital, Denmark Hill, London, S.E.5 (September 16).

Reader (preferably with a science degree or a degree in architecture, and relevant research experience) in Building Science in the Newcastle Division of the University of Durham—The Deputy Registrar, University Office, 1a Kensington Terrace, Newcastle-upon-Tyne, 2 (September 21).

Senior Lecturer (with a medical qualification and good experience in clinical biochemistry) in Chemical Pathology at the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1, or The Registrar, University of Otago (London and New Zealand, September 30).

Reader in Human Genetics in the Department of Zoology, University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (October 15).

Director of the Poultry Research Centre, Edinburgh—The Secretary, Agricultural Research Council, Cunard Building, 15 Regent Street, London, S.W.1 (October 31).

Lecturer (with a degree in science or agricultural science, with some experience in research and teaching in plant pathology) in Botany at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (October 31).

Assistant Biochemist, Basic grade (preferably holding the A.R.I.C., the Grad.Mem.R.I.C. or B.Sc.(Hons.) in chemistry or biochemistry) in the Group Laboratory at Crumpsall Hospital—The Hospital Administrator, Crumpsall Hospital, Manchester 8.

Assistant Experimental Officer (with a pass degree, preferably in zoology and chemistry) for biochemical research on fisheries problems—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, Berks, quoting Ref. 61/24.

Assistant, Grade B (with qualifications and experience to teach mathematics for Diploma in Technology courses and for degree courses in engineering and general science) in Mathematics—The Registrar (Dept. F), Bradford Institute of Technology, Bradford 7.

Assistant Physicist (with at least an H.N.C. in physics, or equivalent qualification) on the staff of the Area Chief Chemist located in Birmingham, for duties involving interesting work on instrumentation in a modern laboratory, together with development and maintenance of instruments associated with gas making plant—The Industrial Relations Officer, West Midlands Gas Board, 6 Augustus Road, Edgbaston, Birmingham, 15.

Assistant Professor (with a Ph.D. or equivalent, and preferably a background and experience in marine biology) of Biology to give instruction primarily in animal physiology—The Head, Department of Biology, Memorial University of Newfoundland, St. John's, Newfoundland, Canada.

Graduate Research Assistant (with an interest in organic chemistry) in the Department of Chemistry—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8.

Histologist (with an honours degree in physiology or zoology or equivalent qualification, and preferably previous experience in histological methods) in the Physiology Department to be in charge of the histological work of the department, and to collaborate in research mainly in the field of endocrinology—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, Berks, quoting Ref. No. 61/25.

Lecturer (preferably with experience in the field of infra-red spectroscopy) in Organic Chemistry for work up to Dip.Tech. and Grad.R.I.C. Part II level—The Registrar, Bristol College of Science and Technology, Ashley Down, Bristol, 7, quoting Ref. No. CST/61/32.

Lecturer (well qualified, and preferably with both teaching and research experience) in Inorganic Chemistry—The Academic Registrar, Loughborough College of Technology, Loughborough, quoting Ref. 21/2/AF.

Lecturer (with appropriate qualifications and experience of carrying out practical research work in the field of clinical psychology) in Psychology—The Secretary, Institute of Psychiatry, The Maudsley Hospital, Denmark Hill, London, S.E.5.

Physicist/Physical Chemist (with a university degree and some experience in the conduct of research) to undertake research in connexion with problems in food manufacture—The Director of Research, British Food Manufacturing Industries Research Association, Randalls Road, Leatherhead, Surrey, marking envelope "Private and Confidential".

Postgraduate Research Assistants (with a degree in biochemistry, chemistry, physiology, physics or zoology) in the Department of Physiology and Biochemistry—The Secretary and Registrar, The University, Southampton.

Radiobiologist (with a knowledge of dosimetry, and preferably a background in entomology and/or invertebrate zoology) for research and development on biological effects of ionizing radiation for application in a long-range biological control programme—The Director, Instituto Venezolano de Investigaciones Cientificas, Apartado 1827, Caracas, Venezuela.

Research Assistant (with an honours degree in botany) to collaborate in compiling a Flora of Turkey—Dr. P. H. Davis, University Department of Botany, Royal Botanic Gardens, Edinburgh, 3.

Research Fellow (honours graduate with special qualifications in botany, biochemistry or microbiology, and preferably experience of radiochemical techniques) in Plant Physiology in the Department of Biological Sciences, to undertake research in algal metabolism—The Registrar (Department F), Bradford Institute of Technology, Bradford 7.

Research Students; Research Assistants (with a good honours degree or Graduate Members of the Royal Institute of Chemistry) and Postdoctoral Fellows in the Organic Chemistry Section of the Department of Chemistry for work concerned with (1) photochemical reactions of aromatic compounds, or (2) the chemistry of unsolvated organomagnesium halides—Dr. D. Bryce-Smith, The University Reading.

Scientific Officer, Chemist (not above 45 years of age, with a first- or second-class B.Sc. honours degree in chemistry, or A.R.I.C. or F.R.I.C., with postgraduate experience preferably in food chemistry and insecticide analysis) in the Federal Ministry of Commerce and Industry, Federal Government of Nigeria, to undertake chemical work pertaining to the deterioration and protection of raw foodstuffs during storage in Nigeria—The Recruitment Attaché, Nigeria High Commission, 9 Northumberland Avenue, London, W.C.2, quoting Ref. E/C3239/1.

Senior Laboratory Technician, Grade I (with appropriate qualifications and experience)—The Head Master, King Edward VI School, Southampton.

The Battery Operated POTENTIOMETER RECORDER that is *COMPLETELY PORTABLE*

Available with Ministry of Power Certificate of Intrinsic Safety

The applications listed are examples of Potentiometric measuring and recording hitherto impossible in the industrial field. That they *are* now possible is due to this transistorised instrument which, with its built-in battery power supply is completely independent of mains current and leads (with their consequential limitations). Very few instruments can claim to have had such a marked record of technical success in such a wide field of industrial and scientific achievement. The MERVYN Battery Operated Potentiometer Recorder claims exclusively to be both *completely portable and self contained*.... it weighs only 17 lbs.

- Internal Battery Power Supply has a life of 250 hours.
- Low Drift Transistor Chopper operating at a frequency chosen to minimise 50-cycle interference
- Battery-driven motor for the combined Potentiometer and Writing Drive
- Transistorised amplifier and voltage reference from Zener Diode
- Inkless Recording using 7-day clock mechanism

The ranges acceptable are from 0-5 mV up to 0-1 volt, by Interchangeable Range Cards

This unique water still is in use in a number of research establishments and hospitals where water of the highest purity is essential

PRICE, complete with heater and all electrical equipment 230 volt (a.c. only)—**£30-0-0**

Inclusive of carriage and packing in U.K.

Obtainable only from

L. V. D. SCORAH, M.Sc.
(Manufacturer of the "SCORAH" Blowpipe)

44 NORTHFIELD ROAD, KINGS NORTON,
BIRMINGHAM, 30. KINGS NORTON 1885

The SCORAH Automatic Electric all glass WATER STILL (patented)

Automatic Can be left on without attention. Heater current cuts off if water supply is interrupted, or inadequate or forgotten. When receiver (5 litres capacity) is full, current cuts off. When distilled water is drawn from receiver, the still resumes operation until receiver is refilled.

Purity Electrostatically charged condenser droplets can pick up fumes, dust and air-borne organisms from the laboratory atmosphere. The design of the receiver vessel ensures absence of such contamination.

Efficiency Heater of Scorah design and manufacture, consumption 1,700 watts, output 2.4 litres per hour (the full theoretical yield). Cost 3½d. per gallon at 1d. per unit.

Safety The heating element is out of contact with the feed water, thus eliminating danger from "live" water supply or electrolytic effects or "burn out".

Assembly No retort stands or clamps are required. The 2½-in. diameter ball joint gives a strainless set-up. Outlet cap on boiler for quick periodical drain-off of sediment. The still may be installed on a shelf or platform about 1 ft. above bench level near a sink and enclosed in a transparent plastic cover to keep out dust.
Phoenix heat-resisting glass. Interchangeable ground glass joints.

APPOINTMENTS VACANT

UNIVERSITY OF SYDNEY
NUFFIELD FOUNDATION RESEARCH FELLOWSHIPS—SCHOOL OF ELECTRICAL ENGINEERING

Applications are invited for two positions of Nuffield Foundation Research Fellow in the School of Electrical Engineering. Candidates should be well qualified in electrical engineering or physics with general experience in electronics and considerable detailed knowledge of solid state circuits. The successful applicants will be associated with the development of electrical engineering aspects of the design of a large radio-astronomy interferometer system under development by the Radio Astronomy Centre, a joint project of the Schools of Electrical Engineering and Physics. The main field of interest will be the application of solid state circuitry to radio-astronomy receiver systems. In each case, the salary will be £A.1,950 per annum and the appointment will be for a period of three years. No allowance will be made to appointees for their travelling expenses to Sydney.

Applications, giving details of qualifications and experience and the names of three referees, should be forwarded to reach the undersigned not later than September 30, 1961. In addition, overseas candidates are required to forward two copies of the application to the Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1, from whom further information may be obtained.

M. A. TELFER,
Registrar.

University of Sydney,
Sydney, New South Wales,
Australia.

UNIVERSITY OF NEW ENGLAND
LECTURER/SENIOR LECTURER IN BOTANY

Applications are invited for the position of either Lecturer in Botany or Senior Lecturer in Botany. Applicants for the Lectureship should hold the degree of Ph.D. and in the case of the Senior Lectureship, should have this degree as well as publications to their credit. Copies of publications can be sent with the application. The successful applicant will be required to lecture in plant physiology or in mycology-microbiology to advanced students in botany and to supervise research projects of postgraduate and final-year (botany double major) students. The successful applicants must be prepared to devote the remainder of his time to research in his particular field of interest. Commencing salary will be within the range £A.1,730 by £A.105 to £A.2,435 for a Lecturer and £A.2,550 by £A.95 to £A.3,000 for a Senior Lecturer, and in addition a cost of living allowance which is at present £A.42, is payable. Provision is made for superannuation, travel and removal expenses and assistance in buying or building a house.

Further information may be obtained from the Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1. Applications close, in Australia and London, on October 6, 1961.

UNIVERSITY OF WESTERN AUSTRALIA
SENIOR DEMONSTRATORSHIP IN ZOOLOGY

Applications are invited from graduates for appointment to the above-named position, which has a salary range of £A.1,400 by £A.50 to £A.1,700 per annum with superannuation similar to F.S.S.U. The position offers primarily a teaching appointment and the appointee will be responsible for organizing and supervising laboratory classes. Facilities will be available for research provided it does not interfere with teaching duties.

The appointee is required to take up duties by January, 1962. Conditions of appointment are obtainable from the Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1. Applications close in Australia and London on September 30, 1961.

RESEARCH BIOCHEMIST

Bob Martin Ltd. seek the services of a young female Research Biochemist. The position would suit a recent graduate but some experience of vitamin and chromatographic techniques would be an added recommendation.

Apply, giving details of qualifications and experience, to the Chief Chemist, Bob Martin Ltd., Southport, Lancs.

COMMONWEALTH OF AUSTRALIA

DEFENCE STANDARDS LABORATORY

The Department of Supply invite applications for the following permanent positions at the Defence Standards Laboratories, MELBOURNE:

RESEARCH CHEMIST

POSITION.—Higher Experimental Officer.

SALARY.—£1,761/£1,981 (Australian currency). (A substantial increase may be awarded shortly.)

DUTIES.—Assist in the study of light-sensitive reactions, particularly the stabilization and inhibition of photo-chemical reactions in the presence of oxygen and ozone. Qualitative inorganic chemistry and a study of "photographic" processes form a large part of the work.

QUALIFICATIONS.—Degree or equivalent qualifications in Chemistry, with several years experience. Experience in general analytical, micro-chemical and photographic techniques an advantage.

POLYMER TESTING & ANALYSIS

POSITION.—Technical Officer Grade 1.

SALARY.—£1,390/£1,581 (Australian currency).

DUTIES.—(a) Development of test methods and investigation of material/performance relationships. (b) Micro-chemical analysis of complex materials by inorganic, organic, and physical methods.

QUALIFICATIONS.—Educational qualifications to be stated. Extensive suitable experience relevant to the studies.

CONDITIONS.—These positions offer permanent appointment to the Commonwealth Public Service, and the successful applicants will be required to contribute to the Commonwealth Superannuation Scheme on confirmation of appointment. Under specified conditions, air/sea transport for the appointees and dependants (wife and dependent children) will be provided by the Commonwealth.

APPLICATIONS.—Forms obtainable from the Senior Representative (AV.119/7), Department of Supply, Australia House, Strand, London, W.C.2, with whom completed applications should be lodged by September 4, 1961.

COMMONWEALTH OF AUSTRALIA

DEFENCE STANDARDS LABORATORIES

PHYSICAL CHEMISTS

The Department of Supply invite applications for the following two positions at the Defence Standards Laboratories, MELBOURNE:

POSITION.—HIGHER SCIENTIFIC OFFICER.

SALARY.—£2,036/£2,296 (Australian currency). (A substantial increase may be awarded shortly.)

DUTIES:

(Position No. 55.) Participate in the current programme of research directed to the correlation of chemical structure with biological activity. The work of the Group includes all aspects of absorption spectrometry and the appointee will be initially assigned responsibility for the infra-red field.

(Position No. 110.) Research into physical chemical aspects, in particular the mass spectrometry, of a variety of problems of interest to the work of the Laboratories. These include (a) absorbed layers on active surfaces, (b) high molecular weight compounds, (c) structure determination of physiologically active substances.

QUALIFICATIONS.—Honours degree in Science with Chemistry as a major subject and some post-graduate experience in physical chemistry. For **Position No. 55** familiarity with any branch of absorption spectrometry, including nuclear magnetic resonance, would be an advantage, and for **Position No. 110** familiarity with mass-spectrometry would be an advantage.

CONDITIONS.—Under certain conditions, air/sea transport for the successful candidates and dependants (wife and dependent children) will be provided by the Commonwealth. **ALTERNATIVELY**, consideration may be given to a three (3) or five (5) year contract of employment in Australia. In this case the Commonwealth will bear the cost of return fares together with the cost of removing the successful applicants' furniture and effects up to a maximum cost of £500 (Australian), £250 each way.

NOTE.—Applicants who do not possess the necessary experience, may initially be appointed as Scientific Officer Grade 1, £A.1,541/£A.1,926, and at a later date may be promoted to Higher Scientific Officer.

APPLICATIONS.—Forms obtainable from the Senior Representative (A.V.118/8), Department of Supply, Australia House, Strand, London, W.C.2, with whom completed applications should be lodged by September 4, 1961.

MICROBIOLOGY TECHNICIAN. APPLICATIONS are invited from men or women familiar with the techniques of microbiology. The work involves the investigation of this facet of the properties of the aqueous emulsions of thermoplastics we manufacture. A pension scheme, canteen and social club add to the interest of the post.—Please write to the Personnel Manager, Vinyl Products Limited, Butter Hill, Carshalton, Surrey.

APPRENTICESHIP AND TECHNICAL EDUCATION

THE debate in the House of Commons on apprenticeship and training, postponed from May 8, fell appropriately in the middle of Commonwealth Technical Training Week, to which reference was freely made in the debate. Both the Carr Report on the recruitment and training of young workers in industry and the later White Paper, *Better Opportunities in Technical Training* (see *Nature*, March 4, p. 701), were much in the minds of speakers in the debate, and while few new proposals were made, the debate showed the extent to which opinion on all sides has advanced in the past three years. The purpose of the Commonwealth Technical Training Week was to stimulate thought and action on technical education in all Commonwealth countries, and while the United Kingdom has no grounds for complacency in the matter, any deficiencies are the responsibility of both major political parties. On all sides of the House of Commons there are those who have sought to rouse public opinion to a sense of what is required, and have pressed constructive proposals on successive Governments, but nevertheless of 550,000 young persons who in 1960 in Great Britain entered employment, 420,000 went into unskilled jobs.

In his speech at Guildhall inaugurating the week, the Duke of Edinburgh said that he refused to believe that this is the right proportion either for the individuals concerned or for the country as a whole; and, in opening the debate in Parliament, Mr. F. Lee agreed, adding that there were many who wished to enter apprenticeship but who were denied the opportunity, and that new production methods demand new skills. A nation which does not acquire new skills condemns itself to obsolete production methods and continues to train young people in skills which have lost much of their value. The skill of many of our craftsmen is, Mr. Lee suggested, becoming outmoded, and we need to re-train many of our present craftsmen as well as to train more apprentices.

Mr. Lee, and other speakers in the debate on May 31 and in an earlier debate on apprenticeships a year earlier, on June 30, 1960, stressed the need for the trade unions to take account of these changes in technique, and while Mr. John Hare, the Minister of Labour, who followed, agreed with what Mr. Lee had said as to the importance of training, he emphasized that this is a matter for employers as well as trade unions, and that it is necessary to consider whether our present methods of training will stand the test of the working life of the boy who is being trained. He believes that the time has come for industry to have a fresh look at the content and methods of training, and suggested that the quality of training would be improved if employers made greater use of the facilities available for further education; the whole of Britain should benefit if employers made greater use of block release courses, but, particularly in Scotland, many apprentices do not get the day release recommended in apprenticeship schemes.

Mr. Hare, who rejected the charge that the Government has been inactive in the matter, referred to some progress which has been made since the Carr Report was discussed and the Industrial Training Council established, without suggesting that there is any ground for complacency. On the contrary, he agreed that the real testing time lies ahead, for the number of school-leavers will rise to 660,000 this year and to 720,000 next year. To impress this on both sides of industry, the Industrial Training Council had called a series of conferences throughout Britain, and, following these conferences, regional committees have been set up which will keep under review and encourage arrangements for recruitment and training during the peak years of the bulge. He believes that these committees will be a most valuable reinforcement to the measures already taken to encourage increased training.

The vital question, Mr. Hare insisted, is the quality of training, and this was the keynote in speeches which the Duke of Edinburgh made during Commonwealth Technical Training Week. In opening the week at Guildhall on May 29, he gave four basic reasons why every country should organize its technical training as efficiently as possible. First, the standard of intelligence, competence and workmanship in industry, commerce and agriculture controls absolutely the ability of any country to hold its own in the highly competitive business of international trade. Secondly, even in the least-developed countries, there is growing mechanization in all the public services, such as transport, communications, water, power and light. In the more developed countries, mechanization has gone much further. As a result, there is a growing need for technically competent persons capable of maintaining this increasingly complicated mechanical complex. Thirdly, technical training is essential if individuals are to make the best use of their aptitudes; and fourthly is the need for teachers, especially in technical subjects. Such teachers are not only needed in Britain. It should be obvious that the less-developed countries are less developed because the standard of technical knowledge is not very high, and the United Kingdom has the duty of providing more teachers not only for her own expansion but also for the developing countries of the Commonwealth.

One of the tasks of the week, however, the Duke of Edinburgh added, was to direct the attention of employers, trade unions and technical teachers to the need for bringing the whole complicated, confused, unco-ordinated system of apprenticeship and technical training in Britain up to date; or, where no system exists, to work out a sensible arrangement quickly. Until the Carr Report appeared, that was a controversial issue; but no feature of the debate on May 31 and the similar debate in June of last year has been more welcome than the evidence of a disposition to re-examine this question. Commonwealth Training Week should certainly encourage this development. In the House of Commons, not only was the rigid five-year period for apprenticeship challenged as irrelevant to modern conditions, but also some constructive suggestions were advanced. Mr. John Robertson believes that apprenticeship should be considered as a continuation of full-time education and transition from class-room to workshop made less abrupt. He would put training under the control either of education authorities or of joint apprenticeship committees representing both sides of industry and the education authorities.

The latter suggestion appears to be a move towards apprenticeship to an industry rather than to a firm, a suggestion which has already found expression in Parliament and was clearly in the minds of other participants in the debate. Mr. Robertson recognized that some measure of compulsion such as day-release might be necessary, and, coming from an experienced trade union organizer, intimately associated with skilled industrial workers and well aware of their problems and outlook, his speech is surely significant. He admitted frankly that long-established customs and practices in industry may need to be changed, and pointed specifically to the lack of knowledge of the numbers and categories of apprenticeships and to the widespread support on both sides of industry for a national register of apprentices; he also suggested in this connexion that raising the school-leaving age might be helpful.

Two other constructive speeches in the debate may be mentioned. Mr. R. L. Mawby looks for more mobility of skilled labour and advocated re-training of skilled workers to this end. While he was less concerned about the five-year period of apprenticeship—though he urged the need for greater flexibility—he was concerned about the quality of the training given during those years and rightly urged that this is what really matters. The importance of skill is increasing, and industry should see that the right incentive is given to new apprentices to acquire new skills. He seemed more hopeful than most speakers about the Industrial Training Council, if it is adequately strengthened and supported.

Mr. R. E. Prentice, whose speech was particularly welcomed by the Parliamentary Secretary to the Minister of Labour, Mr. P. J. M. Thomas, in concluding the debate, was concerned especially with the challenge of the bulge and the opportunity it affords, but urged that much more attention must be given to the question of what constitutes a proper apprenticeship or proper industrial training in the second half of this century. He began, like most speakers, by challenging the rigidity of a five-year period for apprenticeship, and urged that more attention must be given to standards of training and that we need to train many more people to handle a wide range of skilled work.

A feature of the debate was, in fact, this recognition of the need for greater flexibility, but Mr. Prentice made once again his suggestion for some kind of differential training levy rather than the pay-roll tax proposed in the Budget last April, which he thought is likely to discourage apprenticeship schemes. The differential training levy, as operated in France for many years, could penalize the firm which poached trained workers and did not train its own, and assist the firm which did its full share or more of training. He was doubtful as to the value of an apprenticeship council, but thought that the Industrial Training Council needs more staff and resources.

The Parliamentary Secretary welcomed the emphasis on flexibility and stressed that the key to the situation at the craft-level lies in the willingness of employers and unions to increase the intake of apprentices. He also said that the establishment of a national craft apprenticeship system is a long-term process; he did not comment on this proposal for a differential training levy. He welcomed many of the suggestions, however, and particularly the references made to the relation between training in technical colleges and industrial training, to which Miss J. M. Quennell had directed particular attention; he urged the need to consider the strains and stresses which the situation is placing on technical colleges in Britain and the importance of further inquiry into the field of technical education and industry's future requirements for technicians. But he was as firm as Mr. Hare that training should not be completely divorced from production and that industry must accept its training reponsibilities. The Government's efforts should be designed to reinforce and not supplant industry's own efforts.

When the pay-roll clause in the Finance Bill was debated in the House of Commons on June 13, Mr. Prentice did not press his plea for a training levy, though he again referred to it; but he strongly urged that surcharges should not be payable in respect of employees under eighteen. Mr. R. E. Carr also urged that the pay-roll tax should be dropped. But in replying for the Government, the Financial Secretary to the Treasury, Sir Edward Boyle, would go no further than admit that if the surcharge came to be imposed, there would be a strong case for special treatment for boys and girls under eighteen. Sir Edward declined to enter into a firm commitment to provide partial or total relief for boys and girls under eighteen, but promised that the arguments advanced would be kept in mind.

Miss Quennell, who was among those who challenged the appropriateness of a five-year apprenticeship, suggested that the technical colleges could play a greater part. First-year apprenticeship courses are indeed being introduced in some technical colleges and the proposals of the White Paper on technical education are intended to help generally here, not only by improving selection and broadening the content of courses, reducing wastage and filling in gaps in the existing arrangement, but also especially by stimulating co-operation between the education authorities and both sides of industry. The implication of the policy set forth in the White Paper and of the new routes to further education which it provides were indeed discussed in a series of four papers presented at a conference on April 19 arranged by the British Association for Commercial and Industrial Education*.

In the first of these, Mr. G. E. Manning stressed the importance of good teachers in order to make full use of the potentialities of the secondary modern schools and the technical schools and colleges of Britain. Here the questions of salary and status cannot be ignored. Prof. Boris Ford directed attention to the danger that an elaborate system of regional examining boards might destroy the individuality and diversity of our modern schools as well as depress the majority of children who are not good at working at subject examinations. It is important, he said, to encourage the maximum opportunity for independent experiment, and he thought we should work towards a national policy of an award for every school-leaver based on comprehensive assessment, and supported (where relevant) by regional certificates awarded on the basis of local examinations moderated regionally. He also insisted that the education of pupils of average or less than average ability between the ages of thirteen and sixteen, which the Minister has now asked the Central Advisory Council to consider, is the most difficult and worrying segment of the educational system of Britain.

Dr. Ethel Venables, who looked at the proposals from an educational point of view, said that the major problem of educating for industry is not one of selection or teaching methods, important as these are, but of how we could encourage the desire to learn. She suggested that the real way to tackle this problem is to recognize that able young people are a national asset, and that they cannot be educated adequately if a sense of purpose is lacking; society in general and industry (including the trade unions in particular) must be ready to reward achievement at all levels. The nature of the goal would vary throughout industry, but much more time must be devoted to general and social studies.

Mr. F. H. Perkins, speaking from the industrial and commercial point of view, stressed the importance of enabling a transfer from a national certificate to a craft course to be made as early and smoothly as possible and also of much closer co-operation between the technical colleges and industry. He, too, referred to the difficult problem of a sufficient supply of teachers, some of whom must come from industry, and to the need for flexibility if operative courses, following suitable selection, were to give useful service to industry. The need for clear thinking and for careful definition of terms was obvious in Mr. Perkins's paper, and some of the speeches in Parliament showed that even now the functions of the technical colleges and of the colleges of technology are liable to be confused.

Nevertheless, the debate on May 31 demonstrated that if, in his appeal for a fresh look at the system of apprenticeship in Britain, the Duke of Edinburgh was not exactly pushing at an open door, there is now a good deal of support for review. Commonwealth Technical Training Week could well go some way towards achieving its aim of getting industry to examine and improve its schemes of training, recruitment and allocation. If employers and trade unions can be induced to take a fresh look at this question of training, putting aside out-of-date attitudes and thinking only in terms of what is relevant in the second half of the twentieth century, it will have been well worth while. The publicity it has received should contribute to that end, for, as the Parliamentary Secretary to the Ministry of Labour rightly said, an interested and informed public opinion is essential; without it, the necessary measures are unlikely to be initiated or effectively implemented. Commonwealth Technical Training Week is at most only a beginning.

It is important, therefore, that full use should be made of the wider interest it has created and the clear public understanding of some of the issues that are involved. There may now perhaps be the less danger that necessary inquiries into methods of teaching already under way will tend to discourage the students themselves, though it is to be hoped that too much emphasis will not be placed on this aspect while the policies of the White Paper are being given effect. The new group in the Oxford University Department of Education which is studying the reasons why comparatively fewer students read for technological qualifications in Britain than in the U.S.S.R. or the United States, the sub-committee of the National Advisory Committee on Education for Industry and Commerce which is examining the organization of sandwich courses, and the investigation at Birmingham under Dr. T. Lupton, of the College of Advanced Technology, with the aid of a Nuffield grant, of the quality of industrial and college training, should provide some of the new knowledge for which Miss Quennell, for example, pleaded; but such investigations must not be allowed to give an impression that so much is wrong with existing teaching that it is not worth while for a student to enrol in a technical institute. Incidentally, in a written answer in the House of Commons on June 15, Sir David Eccles said that his Department is establishing a new branch to give emphasis to educational research generally.

Again, little good is likely to come of the meeting of the Minister of Education with representatives of English local authorities to discuss the status of the colleges of advanced technology unless a well-informed public opinion is available to support whatever decisions may be reached. For the Minister to succeed in making these colleges independent, on university lines, would not of itself suffice to solve all the many difficult problems, and indeed might raise fresh issues in regard to technical education because the regional principle has been insufficiently regarded in creating these problems. Indeed, one major asset of Commonwealth Technical Training Week has been the way in which it has directed attention to technical education as a whole, at all levels, from that of the university department and of the college of technology to that of the secondary modern and technical school. Furthermore, it should have indicated to many how important it is that Britain should play her full part in expanding technical training in the Commonwealth as a whole. It is not sufficient to fill the gaps in the existing system in Britain, to improve the quality of the training given and to extend its scale: we must both provide a reasonable number of places for overseas students in the colleges and universities of Britain, and also supply an increasing number of qualified and enthusiastic teachers for overseas, especially in the less-developed territories.

* British Association for Commercial and Industrial Education. New Routes to Further Education: Papers presented at the B.A.C.I.E. Spring Conference, Senate House, University of London, 19 April, 1961. Pp. ii+31. (London: British Association for Commercial and Industrial Education, 1961.)

That is sufficient reason for urging much closer co-operation between the Ministry of Education, industry, the universities and others concerned with technical training. Firm assurances were given in the House of Commons as to the co-operation between the Ministry of Labour and the Ministry of Education, and Mr. Robert Carr gave convincing reasons last June why technical training in industry should not be made a responsibility of the Ministry of Education, while at the same time he urged as strongly as Mr. Austen Albu, who made the suggestion, the need for closer co-operation between the two Ministries. The Minister for Science, however, is also vitally concerned, through his responsibilities for the Department of Scientific and Industrial Research alone, as is the Chancellor of the Exchequer, through his responsibility for the University Grants Committee.

It will be recalled that the Carr Committee itself recommended greater flexibility in the age of entry to apprenticeship as well as that opportunity for change of employment should not be limited on grounds of age. The strong support which has been indicated for giving the first year's training in the school rather than in the workshop, and the critical look at the quality of teaching in the workshop which was noticeable in the House of Commons, at least as much from the trade union side as from anywhere else, show the extent to which public opinion has moved since the Carr Report appeared, and how largely Lady Gertrude Williams's criteria are becoming accepted: the first—an adequate supply of training vacancies—was thoroughly discussed during the Commonwealth Technical Training Week. The importance of spreading the costs of training more justly over all firms benefiting from the employment of adult skilled men, of ensuring that men capable of learning to do a job are not permanently excluded simply because they missed the opportunity to train when they were sixteen, and of improving the quality of teaching in the workshop, were fully recognized in the recent debate. On exactly how best to achieve these ends there is still room for discussion and inquiry, and perhaps more especially on the further criteria that theoretical instruction should be graded to suit the capacities of pupils. The scientist and technologist must bear a large responsibility for seeing that matters are not allowed to drift and that the co-operation and new outlook made evident during Commonwealth Technical Training Week are maintained. It is welcome evidence of the acceptance of such responsibility that Mr. G. C. Eltenton should devote such a large part of his presidential address on May 23 to the Society of Instrument Technology to consideration of the education and training of the technologist and technician.

WILLIAM HARVEY

William Harvey : Englishman, 1578–1657

By Prof. Kenneth J. Franklin. Pp. 151+5 plates. (London: Macgibbon and Kee, 1961.) 18*s*. net.

FOR three hundred years, Harveian Orations have been delivered annually to the Royal College of Physicians, and several 'orators' have observed that there is little new to be said about Harvey's life and work. Yet within the past few years fresh information has been forthcoming. The discovery of the Harveian Oration for 1662, ascribed to Sir Charles Scarborough, is a pupil's testimony to Harvey's ideals, knowledge and inquiring mind[1]. Dr. Richard Hunter and Dr. Ida Macalpine have assembled data about Harvey's knowledge of neurology and psychiatry[2]. This aspect has been further extended by Mrs. Gweneth Whitteridge, who with great skill, ingenuity and patience has deciphered Harvey's notes on *De motu locali animalium* (1627), being his views on muscular contraction and its control by the brain[3]. Lastly, Sir Russell Brain, in his Harveian Oration for 1959, has given a comprehensive account of "William Harvey, Neurologist", not suggesting that he contributed anything new to neurology, but illuminating him in Sir Thomas Browne's phrase as the "ocular philosopher", "a great observer of man and of nature, and a thinker whose intuition saw when traditional ideas were outmoded, even though he did not always know how they were to be replaced".

A letter of Bishop Brian Duppa to Sir Justinian Isham[5] relates that Harvey paid attention to dietetics and nutrition and would sometimes fast two days together; that the bishop was with him the day before he died; and that Harvey's life "went out like a spark, without any violence or noise at all".

In respect of all this and further additional information, a new life of Harvey was desirable. Prof. Franklin, who has already rendered great service to Harvey's memory by his new English translations of *De motu cordis* and of *De circulatione sanguinis*, the two anatomical essays addressed by Harvey in 1649 to Jean Riolan, jun., has now written Harvey's biography.

In the first place, the author reviews earlier speculations on the circulation, and demonstrates that Ibn an-Nafis (about 1210–88), a learned doctor from Damascus[6], only foreshadowed to some extent the pulmonary or lesser circulation; Servetus discovered it, but this received little attention. The opinions of Columbus, Vesalius, Botallus, Cæsalpinus and Fabricius, who noted the valves in veins, are also discussed. Prof. Franklin's conclusion is that the observations and opinions of the pre-Harveian "circulators in no way diminish Harvey's fame as the independent discoverer of the circulation".

Harvey's life and work are next described, and attention is paid to the importance of Harvey's second great work, *De generatione animalium*. This would have been even more valuable had it not been for the pillage and destruction of Harvey's notes and papers—including a volume on the generation of insects—in his lodgings in Whitehall by the soldiers of the Parliament.

Prof. Franklin writes concisely and lucidly with scholarship and literary grace. The book is well illustrated and produced.

SOUNDS USED BY ANIMALS

Animal Sounds and Communication

Edited by W. E. Lanyon and W. N. Tavolga. Pp. xiii + 443 + 1 12-in. long playing record. (Washington, D.C.: American Institute of Biological Sciences, 1960.) 9.50 dollars.

THE critical and analytical study of the sounds used by animals in communication is a relatively new branch of biology. The reason for this is that only in the past fifteen or twenty years have recording and analytical techniques been developed far enough for the analysis of the extremely complex sound signals which animals use. Moreover, as the technology of microphones, amplifiers and tape recorders improves (as it does year by year) new possibilities for the study and understanding of animal vocalizations emerge.

The present book, edited by Drs. Lanyon and Tavolga, constitutes a valuable and stimulating guide to those interested in this field. There is an introduction by J. T. Emlen, jun., followed by five chapters, each by a different author, these being largely a transcript of the papers presented at a symposium of the American Institute of Biological Sciences, 1958. Since the vast majority of work on animal sounds has so far dealt with birds, this volume is naturally still rather over-weighted on the bird side, but it is noteworthy for three chapters on other groups—one dealing with sound communication in Orthoptera and Cicadidae, by R. T. Alexander; another on sound production and underwater communication in fishes, by W. N. Tavolga; and a third on the influence of sound on the behaviour of amphibians and reptiles, by C. M. Bogart.

All these are valuable interim summaries in rapidly expanding fields. The book starts with a useful though rather too elementary discussion of techniques by P. P. Kellogg. D. J. Borror's chapter on the analysis of animal sounds is also rather slight and elementary for 1960, but it must be remembered that it was written before August 1958.

W. E. Lanyon's chapter on the ontogeny of vocalizations in birds, and that by P. Marler on bird songs and mate selection are both admirable and forward-looking contributions, suggesting new experiments and new lines of thought. N. E. Collias contributes a very stimulating chapter in which he sets forth an ecological and functional classification of animal sounds, based on wide knowledge and reading. He suggests that the various acoustic signals of animals fall readily into ecological and functional categories related to: (1) food, (2) predators, (3) sexual behaviour and related fighting, (4) parent–young interrelations and (5) aggregations and group movements. He points out that the same sound may have more than one specific use, depending on ecological context, and sounds with similar functions, even when produced by different mechanisms and different animals, are frequently characterized by certain common properties in their physical structure. The book concludes with a chapter by Charles F. Hockett devoted to logical consideration and the study of animal communication. This is a helpful contribution, but it is perhaps written rather too largely from the point of view of a student of human language.

A most important and valuable feature of the book as a whole is that a 12-in. long-playing record is issued with it. This provides precise audio-illustrations of the chief points raised by the seven main chapters and brings to life many of the diagrams. As a result the book is immensely more valuable and intelligible than it otherwise would have been. It is to be hoped that the practice of issuing records with books on this and similar subjects will be widely adopted.

W. H. THORPE

ANALYSIS OF ORGANIC COMPOUNDS

Organic Analysis

Vol. 4. Edited by John Mitchell, Jr., I. M. Kolthoff, E. S. Proskauer, and A. Weissberger. Pp. vii + 429. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1960.) 102*s*.

VOLUME 4 of this well-known series of publications on organic analysis gives further authoritative information regarding the application of the newer instrumental techniques and procedures.

H. Foster presents a detailed account of the principles and usages of nuclear magnetic resonance spectroscopy, and comments also on the limitations of the method. The basic principles utilized in interpreting high-resolution nuclear magnetic resonance spectra are discussed for the case of pure compounds, for example, ethanol, and also for hydrocarbon mixtures. Molecular association, gem splitting, chelation, geometrical isomerism are all illustrated by reference to typical resonance spectra; the effect of the too often ubiquitous presence of water impurity is commented on, and nuclear magnetic resonance investigations on a number of complex substances, for example, Feist's acid, steroids, alkaloids, etc., are detailed.

Nogare and Safranski have provided a most comprehensive review of the applications of gas-liquid chromatography. Theoretical principles, modern apparatus and techniques, detectors, etc., are described in great detail, and considerable reference is made to many varied and important investigations. Programmed temperature and high-temperature gas chromatography receive special treatment.

One rather unique chapter by Krc deals with crystallographic methods, and indicates the valuable information which is yielded by a combined microscopical and X-ray diffraction examination of a given substance. The value of morphological studies of polymorphic modifications, optical properties, fusion behaviour, etc., are all clearly illustrated. The experimental pitfalls associated with the application of the powder X-ray diffraction technique to the identification of organic crystalline materials are indicated. The chapter contains an excellent survey of fundamental crystal optics, morphology, use of Miller indices, etc.

Neilands contributes a welcome review chapter on enzymes, their availability and their varied analytical and clinical usages. He supplies a valuable bibliography of specific applications, for example, estimation of ethanol in blood, detection of peroxides, analysis of specified amino-acids, etc.

The wide use of organic peroxides and ozonides by many industries has resulted in the production of a timely review by Martin on the determination of these occasionally hazardous reagents. The adventitious formation of peroxides in ether solvents is discussed, and the use of an activated alumina column for solvent desensitization and purification is worthy of note.

Iodometric, colorimetric, polarographic, infra-red and other related techniques for peroxide determination are described in reasonable detail, and some attention is paid to the estimation of peroxide mixtures using chromatographic or counter-current distribution separation procedures. Analytical interferences produced by sulphur compounds, conjugated diolefins, aldehydes, etc., are defined: the polarographic method of analysis is considered the most widely applicable method for peroxides generally.

The present volume ends with a chapter by Ke on the applications of differential thermal analysis to the examination of high polymers. The apparatus is described fully, and the thermograms are interpreted in terms of conventional thermodynamic parameters. Applications of this powerful technique to work on synthetic and natural polymers are clearly and extensively demonstrated.

This new volume of the *Organic Analysis* series will undoubtedly be as eulogistically received as were its predecessors. It presents, in a small compass, a considerable amount of information on the theoretical and practical aspects of the six important subjects reviewed, and provides material which will undoubtedly be of the greatest interest to the industrial chemist, the research worker and the academic student.

D. T. LEWIS

STILL MORE NUCLEIC ACIDS

The Nucleic Acids

Vol. 3. Edited by Erwin Chargaff and J. N. Davidson. Pp. xvi + 588. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.) 18 dollars.

WHEN the first two volumes of this book were published, it was evident to the editors that the research on this subject was expanding rapidly, but even they did not anticipate the explosion which has since followed. In an attempt to bring their treatise up to date, they have now issued Volume 3, which has as its object the covering of certain aspects of the subject which had been neglected in the original volumes, or which have recently assumed particular importance. The editors should be congratulated on their decision to take this course, and the third volume of this series will certainly prove a valuable addition to many libraries. They might, however, consider at this time whether it would not be more useful to begin a new series, similar to *Advances in Protein Chemistry*, which would provide definitive articles on recent aspects of the subject and not involve so much delay in publication, rather than to continue this series. It is certainly unlikely that the compiling of a comprehensive and up-to-date text-book on nucleic acids will be feasible for many years.

The new volume is a sort of compromise between a text-book and a review. All the contributors are actively engaged in research on the subjects covered in their contributions, and while this certainly makes for authoritative articles, there is the concomitant risk of the authors giving a one-sided view of the subject. For example, someone reading Schuster's article on virus ribonucleic acids might get the impression that research on this subject began about 1954, whereas the pioneering work of Bawden and Pirie, who first discovered ribonucleic acids in a number of plant viruses some twenty-five years ago, is not referred to, though some of their later work is. Max Schlesinger, a neglected pioneer if ever there was one, is not even mentioned in an otherwise admirable chapter on bacteriophage nucleic acids written by Sinsheimer, though Schlesinger was not only the first person to purify a bacteriophage but was also the first person to identify nucleic acid in any virus. Sinsheimer devotes tantalizingly little space in this article to his own work on the single-stranded deoxyribonucleic acid of the bacteriophage $\varphi X174$, which demonstrates quite convincingly that complementary filaments of deoxyribonucleic acid are not essential for the transfer of genetic information.

Sadron's contribution is largely devoted to light-scattering and hydrodynamical methods of investigating nucleic acids which do not have enough resolving power for polydisperse solutions. However, some of the problems which he poses have since been solved by the elegant methods of Meselson and his colleagues, which unfortunately are too recent to have been included in this chapter, though they are touched on elsewhere. The photochemistry of nucleic acids is covered in considerable detail by Shugar, who also provides a useful list of recommended volumes for extra reading. Khorana reviews both the chemical and enzymic synthesis of polynucleotides, a subject to which he has contributed so much, both directly and by his synthesis of substrates, but surprisingly he omits mention of the enzymic synthesis of small polynucleotides by the reversal of the action of ribonucleases.

The chapter by Hoagland on nucleic acids and their involvement in protein synthesis is most welcome as an authoritative review of this important work, much of which has come from his laboratory, while Gros describes related happenings in bacteria.

The effects of 'antimetabolites' on nucleic acid metabolism, which a few years ago gave so much hope, unfortunately unrealized, of a rational approach to the control of many serious diseases, are covered by Handschuhmacher and Welch. Unexpectedly, this work has made a real contribution to our knowledge of nucleic acid metabolism which could scarcely have been obtained by other means.

A compendium of the analyses of microbial nucleic acids is given by Belozersky and Spirin (it is most encouraging to see a contribution from the U.S.S.R.), and the biosynthesis of purine and pyrimidine nucleotides is covered by Buchanan and Crosbie respectively. Finally, Lajtha gives a short review of the effects of ionizing radiations on nucleic acid metabolism.

ROY MARKHAM

KENNAWAY AND THE CARCINOGENS*

By Prof. ANTOINE LACASSAGNE
Institut du Radium, Paris

I FIRST met Ernest Kennaway in 1923 at the Cancer Hospital in London when he was working on the isolation of the active carcinogenic principles in tar. In the following year Kennaway began to publish the results of the researches; the importance had escaped me a year earlier, yet the discovery of a 'carcinogenesis factor', by the pyrolysis of various organic substances, was to prove one of the most fertile in the whole of cancer research. It supplied the solution to a riddle which for more than 150 years had puzzled clinicians confronted with 'industrial cancers', but unable to understand how they arose. It opened the important chapter of chemical carcinogenesis which was to be written over the ensuing years by Kennaway himself (as director of the Research Institute of the Cancer Hospital and professor of experimental pathology) and the team of brilliant co-workers with whom he had surrounded himself. Through this work, organic chemistry was to be enriched by hundreds of new substances, and the way opened to the prophylaxis of industrial cancers.

During this time my own attention had been directed towards the study of carcinogenesis by endogenous chemical substances, that is to say, by certain steroid hormones. The structural relationship of these substances with the polycyclic hydrocarbons, the carcinogenicity of which had been demonstrated by the workers at the Cancer Hospital, had finally brought home to me the outstanding importance of Kennaway's discovery. But when I came to spend some days in his company at Oxford, in 1950, he was already gravely ill. We were among the twenty or so participants in a colloquium on the geographical pathology of cancer, held during July 29–August 4, following the International Cancer Congress in Paris and the International Radiology Congress in London. His wife was also present, sustaining the sick man with that affectionate companionship and scientific collaboration which she had lavished on him for thirty years, combined with the tenderness of a sister of mercy. Thanks to her, he retained to the end of his life what for a man like Kennaway was a true consolation—the ability to continue his work.

Great scientific discoveries come about by two means. Some are born of almost magical intuition and good fortune, suddenly laying bare a whole unsuspected realm of Nature. Others are reached by patient work and devoted attention to a particular problem. Kennaway's discovery was of the latter kind.

The observation made at the end of the eighteenth century by the British surgeon, Percivall Pott, of a relationship between the development of certain cutaneous cancers and irritation of the skin by the combustion products of coal tar, had been followed by others. Experimental work on the suspected carcinogenicity of tar, pitch and paraffin was started at the end of the nineteenth century. Not until 1915, however, was a positive and conclusive result obtained, by the sensational discovery by Yamagiwa and Ichikawa. Work was at once started in various laboratories the world over to follow up their results. It was recognized that the mouse was the animal of choice, the most convincing results being obtained in this mammal in the shortest time. The lack of conformity in the results, however, led to the observation that the activity of tars varied according to their origin. Opinions differed as to which of the numerous constituents of coal tar might be responsible for its carcinogenic activity, suspicion being directed against arsenic, the phenols, the pyrrols, aniline, benzidine, anthracene and others. A first pointer came with the recognition that only the highest boiling fractions, distilling at temperatures above 300°, possess carcinogenic activity.

It was to the unravelling of this tangled skein that Kennaway had set himself. His patient and methodical work was to supply a thread which, a few years later, was to lead the workers at the Cancer Hospital, through a rapid succession of discoveries, to write one of the fairest pages in the history of science.

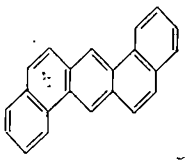
Having observed that compounds distilling at a very high temperature were for the most part hydrocarbons, he had the idea of making a synthetic tar, starting from a very simple organic substance consisting only of hydrogen and carbon. A pyrolysis product of isoprene was tested on the skin of a mouse, with a positive result, and Kennaway's well-reasoned hypothesis was confirmed[1]. Actually, he obtained a higher proportion of tumours than with ordinary coal tars.

In 1925, Kennaway confirmed the results which he had published the previous year, this time using acetylene. The activity of acetylene tars varied according to the temperature at which they were prepared[2]. Other synthetic tars prepared from different organic substances, both animal and vegetable, also proved carcinogenic. In 1930, Kennaway published an even more important observation[3], starting this time from a tetrahydrogenated derivative of naphthalene, tetraline. Under the action of aluminium chloride this pure hydrocarbon acquires new properties, being in fact transformed into carcinogenic compounds. Since the work of Berthelot in 1864[4] it had been known that the pyrolysis of acetylene gives aromatic hydrocarbons by the cyclization of acyclic hydrocarbons. It therefore seemed probable that carcinogenic polycyclic hydrocarbons had in fact been produced in the earlier experiments also.

This hypothesis was confirmed when, in collaboration with Hieger, Kennaway[5] found that carcinogenic tars, whether natural or synthetic, gave a common fluorescence spectrum (three bands at 4000, 4180 and 4400 Å.) to which Mayneord had already directed attention. The fact that a tetracyclic hydrocarbon, 1,2-benzanthracene, had a rather similar spectrum, pointed to another line of inquiry in the search for the causal agent. This was justified when, among the polycyclic hydrocarbons which these authors prepared synthetically, they found one, 1,2:5,6

---

* Substance of the first Sir Ernest Kennaway Memorial Lecture, delivered at the Chester Beatty Research Institute, Institute of Cancer Research, Royal Cancer Hospital, London, on June 12.

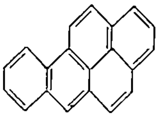


1,2 : 5,6-Dibenzanthracene

(I)

dibenzanthracene (I), which tested on mouse skin produced epitheliomas[6]. The way was open for fresh efforts on the part of the team at the Cancer Hospital, which had now been joined by J. W. Cook.

In 1932, Cook, in collaboration with Hewett and Hieger, had succeeded in isolating from coal tar a pentacyclic hydrocarbon, 3,4-benzpyrene (II), which



3,4-Benzpyrene

(II)

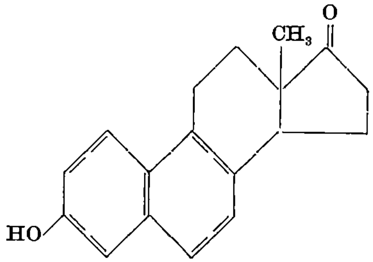
proved to be a much more potent carcinogen than the others previously synthesized[7]. Eight years of methodical work had thus supplied a solution to the problem posed a century and a half earlier.

3,4-benzpyrene seems to be the carcinogenic hydrocarbon produced most frequently and most abundantly in soot from coal fires, in the treatment of mineral oils, and, in certain circumstances, from the combustion of petroleum—all substances derived from the luxuriant vegetable and animal matter laid down during the primary era. 3,4-benzpyrene is also the principal hydrocarbon in cigarette smoke and in the vitiated air of industrial cities. It will be seen that the discoveries of which Kennaway was the author or initiator exercise a continuing repercussion on public life to-day.

They had an immediate influence on the trend of work in all the laboratories concerned with cancer research. While the team at the Cancer Hospital was widening the field of chemical carcinogens, demonstrating the induction of various types of cancer by a very large number of aromatic polycyclic hydrocarbons of differing structure (derivatives of anthracene and phenanthrene), similar teams of chemists and biologists were being formed in the United States, in Germany, Belgium, France, Japan, Norway, Switzerland and elsewhere. In a few years, numerous papers had been published on this subject and many new facts established. The time had come to classify these new data, and in 1937 [8], 1939 [9] and 1940 [10] the team at the Cancer Hospital published invaluable monographs analysing the principal papers and furnishing 877 references to earlier publications.

Since the induction of tumours by chemical means had now been amply demonstrated, it seemed that an understanding of the mechanism of carcinogenesis should soon lie within our reach. The relationship between the molecular structure and carcinogenic activity of chemical compounds was clear. The skeleton of the majority of them contains the phenanthrene ring system; oncogenic activity can be produced, enhanced, weakened or destroyed by simple substitutions on the molecule. It became possible to judge the carcinogenic potency of a given molecule simply from the ring configuration and the position of the substituents. For example, in 1933, Cook[11] predicted the carcinogenicity of a substance which had just been synthesized in Germany, and in the following year he demonstrated this experimentally, in collaboration with Haslewood[12]. The methylcholanthrene (see IV) molecule contains the phenanthrene structure common to numerous compounds the biological activity of which is nevertheless very dissimilar, such as alkaloids, certain cardiac poisons, vitamin D, steroid hormones and bile acids.

The similarity between the skeletons of the carcinogenic hydrocarbons and that of equilenin (III)

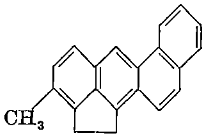


Equilenin

(III)

(a sex hormone discovered by André Girard *et al.* in 1932 in the urine of pregnant mares[13]) did not escape the attention of the research workers in Great Britain. In 1933, Cook and Dodds[14] published their finding of slight, but characteristic, œstrogenic activity of hydrocarbons such as 3,4-benzpyrene and 5,6-cyclopenteno-1,2-benzanthracene.

Was it not therefore conceivable that certain normal metabolites, of steroid structure, might be transformed into carcinogenic compounds in the body itself, as a result of one or more errors of metabolism? It was in fact not long before a new aromatic hydrocarbon, 3-methylcholanthrene (IV) was obtained and



3-Methylcholanthrene

(IV)

found to be even more active than 3,4-benzpyrene: it was produced synthetically from a bile acid, deoxycholic acid (see VIII) by dehydrogenation processes of which the organism is, however, known to be capable.

Kennaway at once perceived the connexion between this finding and an experiment of which he had published the results in 1928 with Sampson[15], and which had yielded tumours using the combustion products of cholesterol. The phenanthrene nucleus is also present in the cholesterol molecule, and it seems that steroid hormones, like bile acids, are built up from this molecule. Kennaway therefore, with his wife and Cook[16], put in hand experiments to demonstrate the carcinogenic activity of deoxycholic acid. It was two years before a single epithelioma was produced in the skin of a mouse; but subcutaneous injection produced several sarcomata *in situ*.

It was in this field of the relationship between carcinogens and hormones that collaboration started between the Research Institute of the Cancer Hospital (shortly to be named the Chester Beatty Research

Institute) and the Institut du Radium in Paris. The work which had been carried out in my laboratory since 1932 on the role of the steroid hormones in tumour induction probably influenced the workers at the Cancer Hospital in their new line of research. It is certain that the most recent publications on the part of these workers caused the line of research at the Institut du Radium to branch in the direction of the study of carcinogenesis by chemical agents.

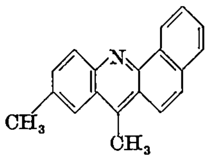
Meanwhile, Burrows, with his skill in histopathology, had proved a most valuable addition to the team at the Cancer Hospital studying induction of cancer by hydrocarbons. From 1935 onwards, he began to specialize in the study of hormonal cancers, and here too his contribution was invaluable. The recruitment of Horning to the Department enriched and accelerated its development. Henceforward I paid frequent fruitful visits to the Chester Beatty, and these two scientists became my firm friends; I cannot recall our cordial relationship without emotion.

I myself meantime had the good fortune to attract to my department a first-class organic chemist, Buu-Hoï. In collaboration with him, I was able to penetrate the vast field of exploration opened up by Kennaway, and to extend the investigations on the mechanism of carcinogenesis which I had pursued first with radiation cancers and later with hormonal cancers. I hope it will not be thought out of place if I now speak a little about the work we had been doing in Paris, which stemmed directly from Kennaway's discoveries.

It was inevitable that we should have to come to compare the action of the carcinogenic hydrocarbons with that of drugs, partly because of the close relationship between carcinogenicity and molecular structure demonstrated by Kennaway, and partly from the idea that the production of radiation cancers might be due to the probable attack on particular targets formed by intracellular organelles. In 1942 we conceived the idea of looking for proof along the lines of Ehrlich's postulate: *corpora non agunt nisi fixata*, already well established in chemotherapy. Thus the classic example of sulphanilamide and *p*-aminobenzoic acid had proved that the fixation of a pharmacodynamic agent on the cell may be disturbed by the presence of a molecule of similar structure. Using pairs of molecules consisting of a polycyclic carcinogen and an inactive or weakly active molecule, acting simultaneously on the skin of the mouse, Buu-Hoï, Rudali and I[17] found that such an antagonism between two hydrocarbons did in fact exist. The most reasonable explanation of the phenomenon seemed to us to be competition between two molecules to attach themselves to the organelle or organelles governing growth and cell division.

This fact has been more or less fully confirmed by several authors. American workers have even shown that certain hydrocarbons, such as methylcholanthrene, inhibit the production of cancer of the liver by carcinogens of very different structure, of the azo group. Two of the members of the active Madison school, the Millers, who have done so much to elucidate the problem of experimental liver cancer, have put forward a very tempting explanation of this observation[18]. With their co-workers, they were able to show that this fixation occurs at the level of certain cellular proteins[19], and thus to confirm that azo carcinogens behave in the same way as pharmacodynamic agents. It has since been found that, in the case of skin cancers, hydrocarbons possess the same capacity for attaching themselves to cellular proteins[20], and from the result of experiments with labelled hydrocarbons it is hoped to determine the quantitative relationship between this capacity and the carcinogenic potency of hydrocarbons. All these results form a solid basis for Kennaway's conception of chemical carcinogenesis.

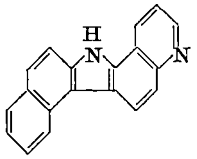
In the course of this work we were led to compare some polycyclic aromatic compounds with various nitrogen analogues. We found that the very large group of heterocyclic compounds analogous in structure to numerous classes of polycyclic hydrocarbons contained an even larger number of substances as active as, or even more active than, the corresponding homocyclic models. For example, the group of angular benzacridines, to which we devoted several years of study[21] includes an even larger number of carcinogens than the related benzanthracenes; a compound such as 3,10-dimethyl-7,8-benzacridine (V) is among the most active substances known.



3,10-Dimethyl-7,8-benzacridine

(V)

More recent work has brought to our notice a fresh class of heterocyclic nitrogenous compounds which promises to be at least as fertile in results as the benzacridine group. This is the azadibenzocarbazole group, some of the members of which are extremely potent, for example, compound (VI).



4′-Aza-1,2 : 5,6-dibenzocarbazole

(VI)

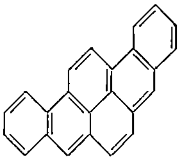
Here, as with the benzacridines, displacement of the heterocyclic nitrogen atom results in a considerable change in biological activity.

One might be tempted to believe that research of this kind, proving as it does that the already considerable number of known chemical carcinogens can be constantly increased, is of purely theoretical interest. In reality, the aim which we had set ourselves from the beginning was very different and very precise: it was to search for a relationship between carcinogenic activity and molecular structure, in the hope of reaching an understanding of the mechanism of chemical carcinogenesis. Earlier authors who had attempted to relate carcinogenic activity to certain molecular structures, such as the position of substituents or the number of rings, had come up against irreconcilable contradictions.

Now, during the Second World War, when France was occupied and only German publications reached us, my attention was attracted by an article by a chemist named Otto Schmidt[22] expounding a theory which appeared to furnish a mathematical explanation of carcinogenesis by polycyclic hydrocarbons, applicable equally to radiation carcinogenesis and even to virus production! The fact that I could not follow Schmidt's reasoning made me the more curious. I questioned the chemists among my friends; each referred me to another more versed in these matters; until finally I met a young theoretical chemist, Raymond Daudel, who was good enough to take an interest in this work. The author explained the differences in the activity of polycyclic hydrocarbons by calculations of wave mechanics. We were thus concerned with a quantum theory, and since, twenty years earlier, my friend the great physicist Holweck and I had been among the first to explain the biological action of radiations by the quantum theory, I was tempted to try to confirm, by experiment, Otto Schmidt's purely speculative idea.

Dare I say that I had fortunately not seen the latest monograph by Cook and Kennaway, published in 1940[10]. I should have been discouraged from undertaking any work in this field, had I read their judgment on Schmidt's work: "These conceptions of Schmidt are of interest, but in the absence of exact data concerning electron densities it is difficult to submit them to experimental test. Moreover, like many other theoretical interpretations they are apt to be more successful in explaining known phenomena than in predicting new ones."

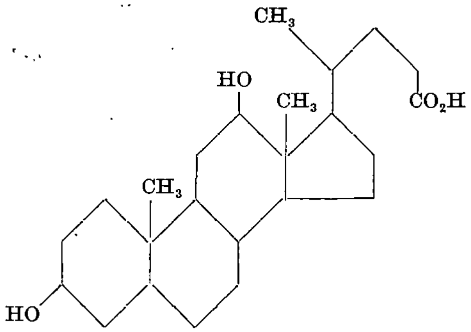
Yet in the twenty years which have elapsed since that time, the rapid progress in theoretical chemistry, aided by the powerful electronic computers, has consolidated the quantum theory of chemical carcinogenesis to the point where it is possible to predict the carcinogenic activity of hydrocarbons before they have been tested. I have neither the time nor the intention to go through the long stages by which the theoretical chemists of the Institut du Radium travelled along this arduous road, thanks to the abundant new material which our organic chemists and experimental biologists had been constantly supplying to the Daudels, the Pullmans and the Chalvets. I may simply recall that it was as a result of the latters' investigations of the electron densities in the molecule of 3,4:9,10-dibenzpyrene (VII), which suggested that this substance might be highly carcinogenic, that we undertook its synthesis and test on the mouse; and it proved to be one of the most potent carcinogens known[23]. The close relationship between this biological property and the molecular constitution of the compound indicates that there is a direct causal connexion between them, as Kennaway had assumed.



3,4 : 9,10-Dibenzpyrene

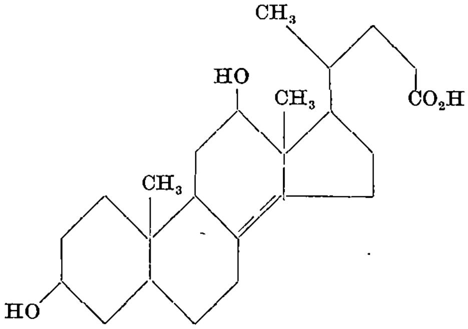
(VII)

Again, quite recently, we have confirmed another of Kennaway's important theses and found that the induction of certain spontaneous tumours may be due to certain metabolic variations in the biogenesis or the catabolism of natural steroids. I mentioned earlier the experiment he carried out with Cook and Lady Kennaway[16], which led to the recognition of oncogenic activity in deoxycholic acid (VIII). This result had not been confirmed by other workers, but in collaboration with Buu-Hoï and Zajdela[24] we have just established that another derivative of cholic acid, namely, apocholic acid (IX), is markedly sarcomagenic, and that this result is reproducible at will.



Deoxycholic acid

(VIII)



Apocholic acid

(IX)

In spite of all this brilliant work, one is obliged to admit that the accumulated research of half a century into the pathogenesis of tumours has still only brought us to the beginning of an understanding of the problem. Nevertheless, one can safely say that the results obtained from the study of chemical carcinogenesis still seem to stand out above all else in this difficult field—even in this era of virus research. They bear witness to Kennaway's worth and to the immortality of his work. His discoveries supplied the scientific bases necessary for the solution of many problems of occupational, preventive and social medicine to which this generous and forward-thinking man dedicated himself during the last years of his life.

I have wondered why I had been chosen to give the first lecture in memory of Sir Ernest Kennaway. Certainly one of the chief reasons must have been the way in which my researches tended in his direction, and the resulting bonds of friendship between the workers at the Chester Beatty Institute and those at the Institut du Radium. But I am inclined to think that account was also taken of the fact that we were contemporaries, he being a few years my senior. We came to maturity during the thirty years preceding the outbreak of the First World War, in a period when the cultivated middle classes, both in Britain and in France, enjoyed complete independence of mind and liberty of action.

It was a period when one could go round the world without a passport, stay at any hotel without filling up a form for the police, profess oneself an agnostic in the political as well as the religious sense without risk of being thought a revolutionary and suspected of a plot to endanger the safety of the State and of society.

We both grew up in an atmosphere where a respect for individual liberty and a veneration for scientific progress were looked on as articles of faith, and we must have been subjected to the same environmental conditions. The two provincial cities where we began our studies were certainly a great distance apart: Exeter, the 'Queen of south-west England', and Lyon, the 'Queen of south-east France'; and yet they are both hard-working industrial towns, with an equally ancient history—*Isca Dumnoniorum and Lugdunum.* In point of fact our scientific careers ran on parallel lines and were devoted purely to impartial research.

I should have failed in my duty if, after paying homage to Kennaway the scholar, servant of human progress, I had not also saluted Kennaway the thinker, who, in philosophy as in science, knew no other guiding star than reason.

SEASONAL VARIATIONS OF CÆSIUM-137 IN AIR AT GROUND-LEVEL

By K. G. VOHRA, V. S. BHATNAGAR and C. RANGARAJAN
Air Monitoring Section, Atomic Energy Establishment, Trombay, Bombay-73

DURING 1956–58 the levels of radioactive fall-out showed substantial increase in the spring season at several places all over the world. This was attributed to the seasonal effects in the mixing between the stratosphere and the troposphere[1,2]. These conclusions were supported by the observed increase in ozone concentrations in the spring season in the northern hemisphere[3]. An alternative explanation of this spring increase in fall-out was given by Martell[4]. According to him, the spring maximum was observed because of the fact that the U.S.S.R. tests were carried out in the autumn of each year and this gave rise to a maximum of activity on the ground in late winter or spring, a period of 4–6 months being necessary for the matter from fall-out to diffuse from the stratosphere into the troposphere and the ground-level air. However, this explanation was based only on the weapon tests carried out in the polar regions and satisfied the data available at that time.

When the nuclear weapon tests were continuing, it was difficult to decide whether the spring increase was due to the weapons testing schedule or natural seasonal effects, or both. The cessation of nuclear weapon tests after October 1958 provided a period of about 15 months when the measurements could be carried out to study the seasonal variations.

We have been collecting samples of air-borne particulate matter on filter papers since early in 1956. These samples have been collected daily at several stations in India and analysed for gross beta-activity[5]. For finding out whether any seasonal variation existed, we started analysis of these samples for cæsium-137. Since cæsium-137 has a long radioactive half-life, the decay of activity on the filter paper during the period of storage was negligible. The daily samples were pooled for individual months, ashed at a temperature of 400° C., and counted for cæsium-137 using a low-level gamma-ray scintillation spectrometer. The cæsium-137 activity was estimated as monthly average concentration in $\mu\mu$c./m.^{3} of air.

Fig. 1 shows cæsium-137 concentrations, gross beta-activity, and ratios of cæsium-137 to gross beta-activity at Bombay for the years 1956–60. The dotted lines show the periods for which data were not available. The ratio of cæsium-137 to gross beta-activity gives an indication of the effective age of the

fission products. Monthly cæsium-137 data for seven other stations in India (Table 1) for the years 1959 and 1960 is shown in Fig. 2, which also includes the levels averaged for all the stations.

Fig. 1 shows that the general trend of variations of the gross beta-activity and cæsium-137 in the air is similar. The peak in gross beta-activity in early 1960 is due to the first French atomic test[6]. The corresponding increase in cæsium-137 due to the French atomic test should be small. Therefore, the increase in cæsium-137 which started in the month of January 1960 and continued until March 1960 should be attributed to seasonal effects. The spring peaks observed in the years 1957, 1958 and 1959 could be due to the combined effects of spring increase and intensive testing of nuclear weapons a few months before the periods showing increase.

The ratio of cæsium-137 to gross beta-activity shows increasing age of the activity after October 1958, when tests were discontinued. However, the ratio shows a sharp decrease during February and March 1960, when the atmosphere contained fission products from the first French atomic test. After March 1960, the ratio increases rapidly, reaching a maximum in the month of June 1960. This also indicates an increase in the concentration of old debris during the months April, May and June 1960.

There are large variations in the levels of cæsium-137 at different stations (Fig. 2), but in general, there is a small increase from late 1959 to early 1960, followed by a decrease. This is more clearly seen in the graph showing the levels averaged for all the stations. This increase is not due to the French atomic test as the contribution of this test to cæsium-137 level in February and March has been estimated to be about 10–15 per cent of the total level from the previous tests. The period of increase at these stations is spread through January to May. These observations may therefore be explained by the seasonal effects in the mixing between the stratosphere and the troposphere as proposed by Stewart[1] on the basis of the Brewer model[7].

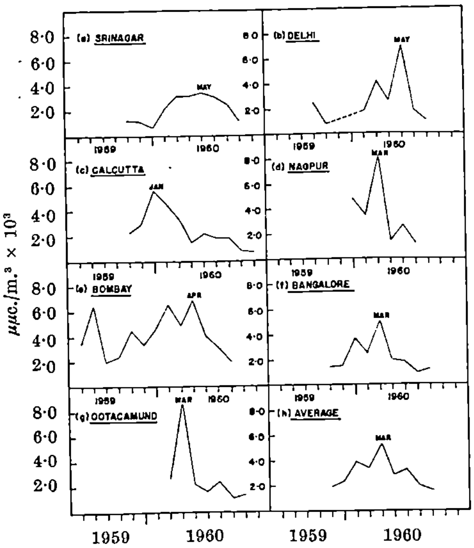

Fig. 2. Cæsium-137 concentration in ground-level air, 1959–60

Recently, there has been evidence from other sources as well on the existence of spring maximum in fall-out[8]. Gustafson has found increased levels of cæsium-137 in surface air during the period April–July 1960, from examination of air filter samples collected at the Argonne National Laboratory[9]. Kuroda, from his work on the concentration of strontium-90 in rainwater[10], and Lockhart, from the measurements of ground-level air-borne radioactivity[11], have also shown the existence of seasonal effects.

A TAKE-OVER BID IN ACOUSTICAL TRAINING

By PROF. E. J. RICHARDS, O.B.E.
University of Southampton

SINCE noise is essentially related to horse-power, and since this latter commodity is increasing rapidly per man in this industrial community of ours, it was apt that the twelfth scientific conference held by the National Physical Laboratory on June 26–28 in conjunction with the Building Research Station and the National Engineering Laboratory on the "Control of Noise" should concern itself with 'unwanted sound', a topic of great current interest and controversy. In his opening remarks the director, Sir Gordon Sutherland, said that just as "beauty is in the eye of the beholder", then "noise is in the ear of the listener". The enormous width of coverage provided during the three days to the three hundred or so delegates followed as a natural corollary and included a series of papers on acoustical measurements and the various objective and subjective units, on the nature of sound sources and methods of

Appearing in August

POPULAR LECTURES IN MATHEMATICS

Translated from the Russian by **HALINA MOSS**

Edited by **IAN N. SNEDDON,** *Simson Professor of Mathematics, University of Glasgow*

I—**The Method of Mathematical Induction** *I. S. SOMINSKII*	7*s.* 6*d. net*
II—**Fibonacci Numbers** *N. N. VOROB'EV*	10*s. net*
III—**Some Applications of Mechanics to Mathematics** *V. A. USPENSKII*	10*s. net*
IV—**Geometrical Constructions using Compasses Only** *A. N. KOSTOVSKII*	10*s. net*
V—**The Ruler in Geometrical Constructions** *A. S. SMOGORZHEVSKII*	10*s. net*
VI—**Inequalities** *P. P. KOROVKIN*	10*s. net*

Each of these books covers a topic in elementary mathematics, starting from the kind of knowledge gained by a student in the early forms at school. Three of these—Inequalities, Fibonacci Numbers and The Method of Mathematical Induction—deal with algebra and cover the topics in a much fuller and more interesting way than is done in elementary text-books; they should be of great value to anyone who is continuing with the study of mathematics either for itself or as a tool in engineering and physics. The remaining three titles deal with geometrical topics and contain much material which is not available in existing text-books.

Although dealing with elementary topics these books approach them from an adult point of view and in addition to being of great interest to school teachers and university lecturers, they should be of interest to people who have long since stopped the study of mathematics, but who now want to learn something of the topics under discussion.

Each book contains problems worked by the authors, all distinguished mathematicians, and exercises to be worked by the reader. In each case there is a section on the solutions of the problems.

The above 6 Lectures are also available bound together in a special Library Edition. 50*s. net*

**Distributed in America by the Blaisdell Publishing Co.*

One Hundred Problems in Elementary Mathematics

H. STEINHAUS

The author aims to stimulate independent mathematical thinking in young people between 14 and 17 years of age, giving examples of the application of mathematics to problems and situations encountered in life, in science, in sport and in business. 30*s. net* ($5.00)

Animal Hormones — A Comparative Survey

Part I—Kinetic and Metabolic Hormones

P. M. JENKIN, *Senior Lecturer in Zoology, University of Bristol*

This is an introductory survey of the sources and actions of vascular hormones in invertebrates, compared with those in vertebrates. Part I covers 'kinetic' hormones—controlling muscles, pigmentary effectors and glands, and 'metabolic' hormones—acting on respiration, diapause, and the balance of carbohydrates, proteins, salts, and water. Part II will cover 'morphogenetic' hormones—controlling growth, differentiation and reproduction. Detailed examples and figures from recent literature illustrate each type of hormonal action, so that the practice, principles and problems of endocrinology are clearly presented for University students, graduates starting research, and teachers. The logical approach to the subject provides a framework within which new material can quickly be assessed.

Post-Graduate Courses in
NUCLEAR SCIENCE
SESSION 1961–62

A. "**RADIATION SAFETY AND HEALTH PHYSICS.**"
(In consultation with the U.K. Atomic Energy Authority.)

1. Seven-months full-time course, leading to College Diploma in Health Physics. Fee: £25 for each part.
   Part 1, January 22 to April 13, 1962.
   Part 2, April 30 to July 20, 1962.

   Part 1 may be taken separately and complies with the U.K.A.E.A. Veale Committee recommendations for Category B courses.

   The Department of Scientific and Industrial Research has accepted the whole course as suitable for the tenure of its advanced course studentships.

   Applications for an award should be addressed to the College.

2. Two-weeks full-time courses, Fee: £12.
   RS16 September 18 to September 29, 1961.
   RS17 November 13 to November 24, 1961.
   RS18 May 28 to June 8, 1962.
   RS19 July 2 to July 13, 1962.

B. **GENERAL COURSES.**

1. RADIOCHEMISTRY, two-weeks full-time October 16–27, 1961. Fee: £12.
2. RADIOBIOLOGY, two-weeks full-time. Fee £12.
   RB2 August 28 to September 8, 1961.
   RB3 January 8 to January 19, 1962.
   RB4 May 7 to May 18, 1962.
3. RADIATION CHEMISTRY, one-week full-time, June 18 to 22, 1962. Fee: £5.

Further particulars and application forms for all courses may be obtained from the Head of Department of Chemistry, at the above address.

suppression, on the ear and hearing conservation, and lastly on community reaction criteria and the possibilities of legislation.

In a way, noise investigations have progressed beyond the stage where large scientific break-throughs are to be expected, and the tone of the conference was therefore one of quiet informativeness rather than belligerent assertiveness. Nevertheless, two items of interest arose time and time again.

The first concerned units, and the need for the establishment of satisfactory criteria of noise-levels which are in keeping with the true subjective reaction of the community. As one speaker lightheartedly put it, "the reason why acousticians are held in disrepute is because they are still arguing emotionally over units. If electrical engineers still regarded electrical current in terms of the nerve stimulus of a dead frog, they equally would be laughed at". Unfortunately, the subjective unit of noise is "emotional" and must include adequately, though maybe not completely, the stimulus of both the ear and the brain. The conference papers did a great deal to pinpoint these basic parameters ; indeed, the papers by D. W. Robinson and Prof. C. W. Kosten were most satisfactory, not so much for their detailed content, as for the impression conveyed that the corner had been turned, and that provided the scientific man-power was available, units acceptable universally to describe aircraft, motor-cycle and factory noises would be put forward during the next ten years.

The second item which needs airing and which was mentioned by many speakers is the provision of trained acoustical engineers. This has up to now been the prerogative of the university physics departments, and it can only be said that both in Great Britain and elsewhere they have taken this duty lightly, even though in fairness it must be said that there are isolated units fighting against the stream of atomic energy and cosmic research at such universities as Durham (Newcastle upon Tyne), London (Imperial College of Science and Technology), Liverpool and Southampton. However, it is significant that since the death of Prof. E. G. Richardson at Newcastle, there has been no single professor of acoustics in Great Britain, and even with the grandiose plans for university expansion there does not appear to be any rush to put right this deficiency. Even at the Imperial College acoustics appears in a lowly place in the expansion process.

Bearing in mind that physicists are being forced to introduce a greater and greater width of fundamental understanding to their students in the three years at their disposal, it may well be that physics departments are justified in this attitude since the basic physics involved in pure acoustics, if not in noise generation, has been established for many years, and the outstanding problems extend into physiology, psychology and engineering as well as into physics. The time has probably arrived therefore when the custodianship of acoustical training should be taken up by the faculties of applied science or engineering and that such a 'take-over bid' should be included in the plans for the next quinquennium. Only in this way can the gross shortage of acoustical and vibration engineers be met.

Such a step is not an unnatural one. Engineering has been defined as the efficient application of the sciences in the interests of the community. Thus a good engineering training, in addition to the teaching of the fundamental sciences and methods of application, also includes some training in economics and in the behaviour of the community. The engineer expects to be interested in 'human engineering', as it is called in the United States, and not only in the purely scientific aspects of his work.

What steps should be taken if the above point of view is accepted ? The establishment at Southampton of a year's postgraduate M.Sc. course in 'vibration and noise studies' to commence in October, and the provision of a readership and lectureship by the Hawker Siddeley Group to support this course is ample evidence of my view. However, a case can also be made out for a 'human engineering' option in the undergraduate stage of the degree in engineering. Such a course could well provide tuition in acoustics, vibration and elementary physiology in the third year in the way that aerodynamics and design, nuclear power and thermodynamics, and hydraulics and soil mechanics is provided now for the aeronautical, nuclear and civil engineer respectively.

Bearing in mind the ever-present practice of putting more and more in a pint pot, the universities themselves favour specialization in the fourth year rather than at the undergraduate stage. However, the pressure from industry for the services of even mediocre students is putting the success of fourth-year M.Sc. courses in jeopardy, and it is to be hoped that industry and the research establishments will themselves see fit to sponsor for such courses students coming into their employ, in order to put right the complaint regarding training so often made at this excellent conference.

OBITUARIES

Dr. Lee de Forest

Dr. Lee de Forest, a pioneer in the history of radio communications and, after much litigation, the acknowledged inventor of the three-electrode thermionic valve, died on June 30 in California at the age of eighty-seven. He was born in August 1873 in the parsonage at Council Bluffs, Iowa, his father being a Congregational minister in that town. Like his father, he graduated from the Yale Sheffield Scientific School in 1896, receiving his Ph.D. degree three years later. While at Yale his interest in electrical phenomena was stimulated by the work of Sir William Crookes and Nikola Tesla and by witnessing demonstrations of Hertz's experiments on electromagnetic waves. In 1899 he went to Chicago to work in the Dynamo Department of the Western Electric Co., and it was there that he became interested in the possibilities of a hot gas or flame detector as an alternative to the coherer then used in wireless receiving circuits.

From this he turned his attention to the Edison effect which he had learnt about at Yale, and which led J. A. Fleming to patent, in 1904, the first diode thermionic valve detector. Two years later, on October 25, 1906, de Forest applied for a patent for a three-electrode valve—a triode—as a device for amplifying weak alternating currents such as were obtained in the reception of radio signals. This was achieved by applying a voltage to the third electrode inserted between the hot filament or cathode, and the plate, or anode. A few months later, de Forest extended the patent to cover the use of the three-electrode valve as a detector.

With a true inventor's imagination, Lee de Forest foresaw some of the possibilities of radio telephony and broadcasting; and, using an arc transmitter at the Metropolitan Opera House in January 1910, he was the first to broadcast opera arias sung by Caruso and other noted artists.

In 1914 the three-electrode valve was introduced as an oscillator and quickly replaced the arc as a source of continuous oscillations for radiotelephony. It was during the First World War, with the great demands it made on radio communications, that the thermionic valve was rapidly developed and applied to the generation of electromagnetic waves at the sending station, and to the detection and amplification of signal currents at both radio and audio frequencies at the receiver. During the period 1919–24, de Forest devoted most of his attention to the problems of talking cinematograph films, and his phonofilm was an early development in this field.

Altogether he held some 300 patents in the United States and other countries, covering such subjects as the guidance of aircraft by radio beams, the wire transmission of news pictures, and the measurement of cosmic rays. He was awarded the Cross of the French Legion of Honour, and his work was recognized in the United States by the receipt of the Edison Medal and Elliott Cresson Medal of the Franklin Institute, and by Gold Medals at the St. Louis Exhibition in 1904 and the Panama Pacific Exhibition in San Francisco in 1915. He was a founder, Fellow and past-president of the Institute of Radio Engineers (New York), the Gold Medal of which he won in 1922. Apart from various scientific papers, Lee de Forest was the author of *Television Today and Tomorrow* and his autobiography entitled *Father of Radio*.

R. L. SMITH-ROSE

Prof. B. Hague

PROF. BERNARD HAGUE died on September 29, 1960, in his sixty-eighth year, having occupied the James Watt chair of electrical engineering in the University of Glasgow since 1946, on the retirement of Prof. G. W. O. Howe. Born at Barnsley, Yorkshire, he received his early education at the Grammar School, Eccles, and at the Central School, Rochdale. He started as a millwright apprentice in Rochdale at the age of fifteen and later served as a junior draughtsman with Messrs. Ferranti, Ltd., Hollinwood. He attended evening classes at Rochdale Technical School from where he obtained an exhibition enabling him to study at the City and Guilds College, London. He graduated with first-class honours in 1915, and in the following year obtained the diploma of the Imperial College of Science and Technology. During 1916–20 he was employed as a technical assistant at the Royal Aircraft Establishment, Farnborough, and he began his teaching career with an appointment as a lecturer at the City and Guilds College after being awarded an M.Sc. degree in 1919. His association with the late Prof. G. W. O. Howe, then a lecturer at the City and Guilds College, led to his appointment as a lecturer at the University of Glasgow in 1923, after the appointment of G. W. O. Howe to the James Watt chair of electrical engineering at that University in 1921.

In 1926 he was awarded the Ph.D. of the University of Glasgow, and became a D.Sc. in 1927 and a Fellow of the City and Guilds of London Institute in 1936.

Prof. Hague was a true scholar of wide knowledge and experience. His intellectual pursuits and admirable personal characteristics earned him the respect of many and the loyalty of his staff. He was the author of books on a.c. bridge methods, instrument transformers, electromagnetic problems in electrical engineering, an introduction to vector analysis and the method of symmetrical co-ordination in the theory of polyphase circuits. His *A.C. Bridge Methods* is still regarded as a reference text and has been translated into several languages.

Hague had a particular clarity of presentation both in his writing and in his teaching and this reflected a thoroughness and sincerity of personal endeavour. He appreciated the visual arts and had a deep interest in music, being himself an oboist of distinction. He was a member of the Royal Musical Association and previously a governor of the Royal Scottish Academy of Music.

Above all, his interest in his students was personal and genuine, and he was ever ready to give of himself to the benefit of others, thereby gaining great respect and affection from all with whom he came into contact.

J. LAMB

NEWS and VIEWS

Chemical Defence Experimental Establishment, Porton : Dr. E. A. Perren

DR. E. A. PERREN has just retired from the post of director of the Chemical Defence Experimental Establishment, Porton, after thirty-eight years service in the War Department and Ministry of Supply. He studied chemistry at the Royal College of Science and obtained his Ph.D. in 1922 for researches in Prof. Jocelyn Thorpe's laboratory on three-carbon tautomerism. He then continued to work with Thorpe, as his assistant, at Porton and was absorbed later into the permanent staff there. He was concerned for many years with research into methods of producing smoke-screens, and the results of this work were put to profitable use during the Second World War. His responsibilities afterwards widened and included spells of duty at headquarters and in supervisory work at the Establishment. During 1948–49 he returned to the laboratory to undertake some research in organic chemistry and was then loaned for two years to the Canadian Government to take charge of its Experimental Station at Suffield, Alberta. In 1955 he was appointed director at Porton and retires with the rank of chief scientific officer. Dr. Perren is to continue to serve the Chemical Defence Experimental Establishment in the research laboratories.

Mr. E. E. Haddon

Mr. E. E. Haddon, director of Chemical Defence Research and Development at the War Office, has succeeded Dr. Perren. Mr. Haddon was born at York in 1908. He was educated at Archbishop Holgate's School, York, and at Queen Mary College, London (then East London College), where he graduated with honours in chemistry. After a short period with the Admiralty, he joined the Chemical Warfare Research Department at the War Office in 1929, and during the Second World War became deputy to the Controller of Chemical Defence Development in the Ministry of Supply. In 1945, on promotion to senior principal scientific officer, he temporarily gave up his association with chemical defence to become secretary to the Scientific Advisory Council and assistant director of technical and personnel administration in the Ministry of Supply. He returned to the field of chemical defence in 1952, when he became assistant director, Chemical Defence Research and Development. Five years later he was promoted to the grade of deputy chief scientific officer on becoming director. Mr. Haddon has been closely concerned not only with the direction of chemical defence research in the United Kingdom but also with the framing and implementation of national defence research policy and with the furtherance of international collaboration in this field.

London Transport Directorate of Research : Mr. A. T. Wilford

Mr. A. T. Wilford, director of research, London Transport, is to retire on June 30. Mr. Wilford was educated at Wilson's Grammar School, Camberwell, and obtained his degree at the Imperial College of Science and Technology. During the First World War he served in the Special Brigade, Royal Engineers, and later with the Royal Field Artillery. He entered the service of the former Underground Companies in 1920 as chemist with the London General Omnibus Co. and became chief chemist in 1926, a post which he continued to occupy under the London Passenger Transport Board. He became superintendent of laboratories when the Laboratory Services of the London Transport Executive were centralized in January 1949, and, in May 1950, he was appointed to the new post of director of research. Mr. Wilford has been responsible for the general direction of research activities and scientific control in London Transport and for liaison in these matter with other sections of the British Transport Commission. The new Research Laboratory at Chiswick, which was officially opened in December 1960, was designed in accordance with his requirements. He has served on a number of committees and for several years was a member of Council of the Institute of Petroleum. He is the author of a number of papers concerning the use of fuels and lubricants in road service vehicles and for one of these he was awarded the Crompton–Lanchester Medal of the Institution of Mechanical Engineers.

Mr. H. E. Styles

Mr. H. E. Styles, who is succeeding Mr. Wilford as director of research, London Transport, is fifty-two. He was educated at Strand School, Brixton, and Battersea Polytechnic, where he graduated with first-class honours in chemistry. He joined the staff of the London General Omnibus Co. laboratory, the forerunner of London Transport's present Research Laboratory, in September 1927. In 1940 he became assistant to the chief chemist and, later, assistant to the superintendent of laboratories. Mr. Styles was appointed superintendent of laboratories in 1950, in charge of the Central Laboratory at Chiswick and three laboratories located at London Transport's Lots Road, Greenwich and Neasden electricity generating stations. During the time he has been superintendent, the activities of the Central Laboratory have expanded, both in volume and range, to such an extent as to warrant provision of the newly erected Research Laboratory at Chiswick, in the design of which Mr. Styles was closely concerned. Mr. Styles represents London Transport on the Standardisation Committee of the Institute of Petroleum, the Illumination Industry Standards Committee of the British Standards Institution and the National Illumination Committee of Great Britain. He is chairman of the sub-committee of the National Illumination Committee concerned with Lighting for Transport.

Mr. Isaac Shoenberg : Silver Jubilee of British Television

Following a recommendation of the Television Advisory Committee, an experimental television service began in London in August 1936, with two systems—those of Baird on 240 lines and of Electrical and Musical Industries, Ltd. (E.M.I.), on 405 lines (interlaced). Three months later a public service was formally opened by the Postmaster General; and in February 1937 the Television Advisory Committee recommended that henceforth only the E.M.I. system should be used. In this way the world's first public television service was inaugurated; and what has been sometimes termed the Shoenberg–E.M.I. system has been used by the B.B.C. ever since. Isaac Shoenberg was born in Pinsk, in Russia, in 1880. After taking his degree at the Technological Institute of Kiev, he joined a Russian company and was responsible for research, design and installation of wireless transmitting stations. He came to England in 1914, becoming a British subject five years later. In 1931 he became director of research of the newly formed Electrical and Musical Industries, Ltd. Mr. Shoenberg led the team of scientists and engineers which, in a remarkably short time, developed the 405-line television system, to substantially the same standards as are in use to-day. Mr. Shoenberg was awarded the Faraday Medal of the Institution of Electrical Engineers in 1954 in recognition of his outstanding technical contribution to the British television service. He was the guest of honour at a reception held recently by E.M.I. at Hayes to mark the silver jubilee of the E.M.I. television system.

Status of the Norfolk Broads

In a written answer in the House of Commons on August 1, the Minister of Housing and Local Government, Mr. H. Brooke, pointed out that the primary responsibility for the designation of National Parks in Britain rests with the National Parks Commission. The Commission had advised him that the unique character of the Norfolk Broads made them in no way comparable in type with the other areas which, in conformity with the general requirements of the National Parks and Access to the Countryside Act, had been designated as National Parks. Mr. Brooke concurred in the Commission's conclusion that designation under that Act would not be appropriate, and he said he had agreed that the Minister of Transport, in consultation with the Minister of Agriculture, Fisheries and Food and himself, will consider the views of the Great Yarmouth Port and Haven Commissioners, the East Suffolk and Norfolk Rivers Board, and other local bodies about the future of the Broads.

International Council of Scientific Unions

THE ninth general assembly of the International Council of Scientific Unions will be held at the School of Pharmacy, University of London, during September 25–28. The general assembly will be preceded by meetings of the bureau and of the executive board to be held in the rooms of the Royal Society, which is the British adhering body to the International Council of Scientific Unions. The last general assembly of the Council held in London was in 1946, the first after the Second World War. While the scientific results of the international effort put into the International Geophysical Year are gradually becoming available, plans are being made by the International Council of Scientific Unions and several of the Unions for the "International Year of the Quiet Sun", April 1, 1964–December 31, 1965. The results obtained during the maximum solar activity period of the International Geophysical Year can only be of full value with a complementary programme at the forthcoming period of minimum activity. The disciplines of geomagnetism, aurora and airglow, cosmic rays and space research are particularly affected. Preliminary work is taking place on an "Upper Mantle Project" proposed by the International Union of Geodesy and Geophysics. There is to be a meeting on the subject in Moscow in 1963. The study of the upper mantle and its influence on the Earth's crust is fundamental to the solution of the outstanding questions of geology and solid earth geophysics, and will include work on deep drilling, deep-sea seismographs, deep-focus earthquakes, magnetic and gravimetric investigations, tectonic and magnetic development of crust, work on changes in phase, thermal conditions and equation of state, and high-pressure laboratory work on behaviour of rocks.

The International Union of Biological Sciences has for some time been discussing plans for an "International Biological Programme". Preparation for the programme will take several years, and a preparatory committee of six members has been set up to establish communication lines with the United Nations Organization, national adhering bodies, and other interested groups, and to formulate a precise programme on the basis of information gained. The "Special Committee of Oceanic Research", set up by the International Council of Scientific Unions in 1957, is planning an intensive investigation of the Indian Ocean. A number of reconnaisance cruises has been carried out; but the main period of activity in the Indian Ocean will be 1962–63. With at least thirteen countries and some forty-three ships, the International Indian Ocean Expedition promises to be more ambitious than the oceanographic contribution to the International Geophysical Year.

First Pamphlet on Clean Air

THE year 1661 may be said to be the beginning of the campaign for clean air. In that year John Evelyn wrote his famous tract, or discourse, *Fumifugium, or the Smoake of London Dissipated.* The work is dated May 1661, and it was presented to Charles II in September 1661. King Charles, Evelyn records in his diary, "was pleased that I should publish it by his special commands, being much gratified with it". The National Society for Clean Air has now reprinted the tract. It is available either as a paper-back at 2*s.* 6*d.* or cloth-bound at 5*s.* (postage 3*d.* or 6*d.* extra) from Field House, Breams Buildings, London, E.C.4. In the Epistle Dedicatory to "The King's Most Sacred Majesty", Evelyn explains how the idea of the book was conceived: "It was one day, as I was Walking in Your MAJESTIES Palace at White-Hall that a presumptuous Smoake issuing from one or two Tunnels neer Northumberland house, and not far from Scotland Yard, did so invade the Court; that all the Rooms Galleries, and Places about it were filled and infested with it; and that to such a degree, as Men could hardly discern one another for the Clowd, and none could support, without manifest Inconveniency". In his preface to the tract, the author waxes eloquent: "That this Glorious and Antient City, which from Wood might be rendred Brick (like another *Rome*) from Brick made Stone and Marble; which commands the Proud Ocean to the *Indies*, and reaches the farthest *Antipodes* should wrap her stately head in Clowds of Smoake and Sulphur, so full of Stink and Darknesse, I deplore with just Indignation".

Measurement of Quality in the Chemical Factory

IN the latest Department of Scientific and Industrial Research booklet which has been produced to extend the application of science in industry, A. J. Clark and C. W. Munday, of the Distillers Co., Ltd., discuss the use of instruments to control processes in the production of chemicals. The authors sum up their attitude with the words, "All chemical plants should have skilled analysts for measuring product quality, and it is indisputable that a first-class analyst is far more versatile than any instrument. However, if it is found that the successful functioning of a process depends on a large number of routine analytical operations, it is worth considering whether an instrument would be a more effective way of doing the job". The advantage of such an arrangement is that the analyst can be released for more creative work, and that continuous control can be exercised without the delay inherent in human supervision. In this booklet, *Quality Measurement in the Chemical Factory*, the emphasis is on instruments of proved worth and relative cheapness, with as wide a range of applications as possible. The authors pay special attention to the use of gas chromatography. Process-stream gas chromatography analysers with a simple repetition time of 1 min. are now becoming available, and, linked to automatic controllers, are already controlling chemical processes. Copies of the booklet may be obtained free from the Department of Scientific and Industrial Research Library, Charles House, 5–11 Regent St., London, S.W.1.

A Soviet View of British Libraries

UNDER the title "A Soviet View of British Libraries", the Library Association has issued as *Pamphlet* No. 22 a report on a visit in October—November 1959 by V. I. Shunkov, G. G. Firsov and N. I. Tyulina, translated by A. Thompson (Pp. 32, The Library Association, London, 1961. 5*s.*). The pamphlet gives an interesting picture of the learned and public libraries as seen through Russian eyes, of co-operation between these libraries, their staffs, organization, buildings and equipment. Of the learned libraries, only the British Museum Library and the National Libraries of Scotland and Wales are mentioned more than in passing; of the university libraries only those of Oxford and Cambridge; and the special libraries are even more sketchily noted. There is no reference to any library maintained by a professional society such as the Chemical Society, and the description of the public library service is likewise extremely condensed, though it is obvious from the comments made that the writers of the report have seen and pondered a great deal they have been unable otherwise to mention. The slenderness of most library staffs is stressed, but in noting the favourable comments on buildings and equipment it should be realized that most of the libraries visited were in new buildings, not always completely finished or equipped.

Japanese Planetarium Equipment

MESSRS. CHIYODA KOGAKU SEIKO K.K., manufacturers of Minolta cameras, have now developed a series of Minolta planetarium projectors. These projectors are distributed in the United Kingdom by Japanese Cameras, Ltd., Tunstall, Stoke-on-Trent. There are four standard projector models in the series priced in the range £7,000—£69,000. Models *S* and III are remote controlled and require a dome the diameter of which is in the range 66–100 ft., while models *MS* and *M* are controlled from a position adjacent to the projector and require a dome the diameter of which is in the range 20–50 ft. Models *MS* and *M* project about 3,000 stars, and projectors are installed for the movements of the planets. These planetary projectors are quite separate in the case of model *MS*, but are coupled in the case of model *M*. Model *S* is similar to model *MS* except that it carries a projector giving 9,000 stars and a separate bright star projector. Model III, the most refined of the series, is similar to model *S* with regard to star projection, but incorporates the coupling of the planetary projectors as in model *M* as well as other devices. Each of the four standard projectors carries an equivalent set of special effects projectors, such as a Milky Way projector, a morning- or evening-glow projector, etc. Model III carries a constellation projector in addition. The standard projectors may be supplemented with auxiliary projectors to reproduce auroral phenomena, the solar system as viewed by an external observer, etc. It is interesting to observe that an auxiliary projector can be provided to illustrate the motion of artificial satellites—a choice of American or Russian being provided. It is to be hoped that the advent of cheaper projectors may encourage the establishment of more planetaria in Britain. Small instruments, not necessarily operating on a commercial basis, could be used to assist the teaching of astronomy in schools and colleges, especially if situated in large centres of population.

Medicine, Science and the Law

THREE papers, which appear in *Medicine, Science and the Law* (1, No. 4; July 1961), contain implications of considerable importance; each is a real advance in the development and refinement of scientific methods of identifying blood. Dr. R. A. A. Coombs and Barbara Dodd describe a microscopical technique which enables them to determine the nature of a stain on a single fibre of clothing or other material. They show that it is now possible to say with a high degree of certainty not only that the fibre is stained with human blood but also to determine, at least within the limits of the *ABH* system, the group to which the blood belongs. The method is applicable to stains of considerable age, certainly up to three years, in the case of human blood. Dr. H. H. Muller and his colleagues have examined the problem of whether stains consist of human or animal blood in a different way. They have evolved a method of testing for hæmoglobin in the stain. Hæmoglobin differs in its minute physical and chemical characteristics from species to species, but it has hitherto been difficult to identify the species from which it came. The method suggested does not give information about the group of the blood in question. Dr. I. Dunsford, R. Lodge and W. Spielmann describe an investigation into blood groups in a paternity case in which, after a detailed examination of the groups of the child and putative father using all the refinements in technique normally available, the blood groups of the putative father fitted the blood groups of the child in every aspect but one. The child's *Rh* constitution was shown to be *CDE*/*cde* and the putative father's more probably *CDe*/*cDE* but possibly *CDE*/*cde* (that is, as in the child). The technique described in their paper enabled the authors to show that the putative father's *Rh* constitution was *CDE*/*cde*, so that he was not excluded. Moreover, the 'fit' of his blood with the child's is so good that (although the authors do not claim it) the scientific evidence points to his being in fact the father.

Blindness in Africans in Northern Rhodesia

IN 1949 territorial ophthalmic services were started in Northern Rhodesia. Before that date very little was known of the incidence of eye diseases and even less about the extent and causes of blindness. In 1950 a simple blindness register card was produced and distributed to all administrative officers, together with a simple memorandum on eye diseases describing the four conditions which are the principal causes of blindness. Dr. C. M. Phillips, Government ophthalmologist, Lusaka, now shows (*Central African J. of Med.*, 7, No. 5; May 1961) that the overall incidence of blindness is considered to be 500–750 per 100,000; in some areas it rises as high as 2,300, with the unique feature of having a higher incidence of onset in childhood than in adulthood. The main causal lesions of 2,701 patients examined are corneal pathology, phthisis bulbi, senile cataract and trachoma. It is considered that the predominant factor responsible for the first two lesions is traditional African medicine. Taking all factors into consideration, it is believed that four out of every five persons who have lost their sight did so from a cause that is either preventable or curable.

Uses of Castorseed

A TWO-DAY seminar on Castorseed and its Products was held during August 11–12, 1960, at the Regional Research Laboratory, Hyderabad, under the sponsorship of the Council of Scientific and Industrial Research, India. In order to consider the various factors bearing on the present and future of the castor industry in India, a number of questions likely to arise were first formulated under suitable heads. These were sent to a large number of research institutions, organizations dealing with castor, and firms either possessing castor or utilizing its products, especially castor oil. Data or information illustrating and amplifying the questions raised were requested. The data, received in the form of brief notes, were arranged suitably under the different heads. These questions and notes were then sent round to all the organizations for thorough study, ensuring that the discussions at the venue would be well informed and fruitful. The entire material has now been brought together in a booklet, *Castorseed and its Products* (Pp. viii + 87. Hyderabad: Indian Central Oilseeds Committee. 1961). It includes the questions raised, the notes received and the discussions which later took place at the sessions. Though the seminar dealt primarily with castor in its Indian setting, the material in this booklet might well have a wider interest.
